Why was integration so limited in this case? An important possibility put forth by the authors is that, as in the clicks task (Brunton et al. 2013), the noise that limits performance in their categorization task may not be of the type postulated by integration (drift-diffusion) models, which represents random fluctuations in activity *within* each trial. Any variability *across* trials would diminish the benefits of integration. But note that any slow signal that sometimes favors one outcome and sometimes the other independently of the sensory evidence would have precisely such an effect. For instance, a preference for making one motor response over the other assigned randomly across trials would work (Brown and Heathcote 2007; Shankar et al. 2011; Salinas and Stanford 2013) and would be consistent with the broad framework outlined above – in which perceptual decisions arise when sensory information and internal motor plans interact to generate informed choices (Cisek and Kalaska 2010).

Perceptual-Motor Dissociation

Andrei Gorea

Laboratoire Psychologie de la Perception,
Université Paris Descartes and CNRS, Paris,
France

Definition

Perception

Intuitively, perception is the process of becoming aware of physical objects or phenomena through the senses. However, to define it as an observable phenomenon without resorting to a highly subjective concept such as awareness, one must include additional measurable criteria. A less involved and more up-to-date view is that perception is the mental function by means of which the physical world (including within body processes) is represented and the process by means of which this function interacts with the physical world, together with the consequence of this interaction. This definition dissolves from the start the perception-action dissociation dilemma: according to it, the two concepts are indissociable.

Motor Event

Any movement caused by the muscles.

Detailed Description

In some sense, the necessity of a tight perception-action coupling has been posited at least since Helmholtz (1867/1962). He proposed that the perceptual stability of our visual world in the presence of continuous eye movements could be due to a *closed-loop* circuitry, whereby the visual-motion signal triggered by the displacement of the retina during an eye movement is cancelled out (up to some error) by the motor signal that induced that specific eye movement. Alternatively, such cancellation can be obtained by subtracting the *predicted* eye-movement *outcome* for a given motor command from the *actual* outcome.

In fact, this so-called *pseudo-closed-loop* scheme is the founding principle of modern *forward models* used in computational motor control (Jeannerod 1983, 1997; Wolpert et al. 1995; Warren 2006; Wolpert 2007). A wealth of empirical and modeling studies do indeed support a fine online interplay between perceptual and motor processes during motor planning and execution (e.g., Paillard 1960; Ingle 1982; Requin et al. 1988; Hommel et al. 2001). However, as this literature does not focus on the cognitive aspects of perception and is not controversial, it will only be alluded to in the remainder.

Opposite Views

Helmholtz's intuition notwithstanding, most of the twentieth-century *perceptual* research (with perhaps Gibson's (1950, 1979/1986) notable exception and that of a few followers) was entirely disconnected from the motor research. By the end of the last century, however, two major streams of thought pervaded both fields of research. In 1982, Ungerleider and Mishkin revealed two major sets of nerve projections in the monkey brain, both originating in the primary visual cortex, one projecting ventrally into the temporal lobe and the other projecting dorsally into the posterior parietal cortex (Fig. 1). They proposed that these two pathways have complementary functions: the ventral (or "what") pathway subserves object identification, whereas the dorsal (or "where") pathway allows spatial localization of these objects. This anatomical dichotomy was extended by Goodale and Milner (1992), who proposed an equivalent functional dichotomy between what they called "vision for perception" and "vision for action." A few years later, O'Regan and Noë (2001) revived Helmholtz's intuition and Gibson's ecological approach, as well as the more philosophical perspective of Maturana and Varela (1987), and documented the opposite view, according to which perception and action are inseparable. In fact, they pushed this view to its extreme, which is that perception cannot exist without action, and vice versa. In defense of this stand, Daniel Wolpert has argued that brains' *only*

Perceptual-Motor Dissociation, Fig. 1 Simplified representation of the two functional pathways for the treatment of visual information according to Ungerleider and Mishkin (1982; following Goodale and Humphrey 1998). Retinal stimulation is transmitted to subcortical structures (SC, Pulv, LGNd) and then cortical structures (PPC, V1). After having reached the visual cortex, information flows

along one of two streams: the dorsal pathway, which leads to posterior parietal cortex and is thought to subserve the visual control of action, and the ventral pathway, which is thought to subserve perception and whose integrity is considered necessary for conscious perception (LGNd lateral geniculate nucleus pars dorsalis, Pulv pulvinar, SC superior colliculus)

function is to sustain adaptable and complex movements, pointing out that originally active, brain-equipped creatures (such as sea squirts) that end up settling down for good on rocks digest their brains once they cease moving (see <http://freethoughtblogs.com/tokenskeptic/2011/12/13/why-we-dont-eat-our-own-brains-professor-daniel-wolpert-on-ted/>). Accordingly, Wolpert's postulate is that all mental processes – sensations, thoughts, and emotions – lead to interactions with the environment that eventually translate into muscle activity.

Arguments in Favor and Against the Dichotomy

Goodale and Milner's dissociative view (Goodale and Milner 1992; Milner and Goodale 1995, 2008; Goodale 2011) was originally based on a type of scientific observation referred to as a "double dissociation." Lesions of posterior parietal areas (dorsal stream) lead to a condition known as *optic ataxia*, which involves disturbances in visually guided action. Patients set before a mailbox slot are able to report its orientation but are incapable of correctly inserting a card into

it. Lesions of ventral visual areas, in contrast, lead to *visual agnosia*: these patients are unable to verbally indicate the orientation of the slot but can correctly insert a card into it. This double dissociation has been challenged based on observations suggesting that (1) optic ataxia is not a general disturbance of visually guided action, (2) visual agnosia is not a disturbance specific to perception, and (3) studies involving such patients were not well controlled (see Pisella et al. 2000, 2006; Rossetti et al. 2003, 2005; Cardoso-Leite and Gorea 2010).

Many other claims favoring a major distinction between perception and action have gone through similar cycles of debate. The dual-pathway theory gained support from various anatomical/imaging, neurophysiological, and neuropsychological studies, including studies based on visual illusions and on priming with allegedly "invisible" stimuli (presumably entailing differential perceptual and motor effects brought about by subsequently presented visible stimuli), and from studies contrasting perceptual and motor response latencies and accuracies. However, the conclusions drawn from such studies have each been rebutted on different grounds. Anatomical/imaging and neurophysiological evidence favoring the

dual-pathway theory was offset by evidence that both ventral and dorsal streams process information about the nature of objects and their locations in space (e.g., Konen and Kastner 2008) and that dorsal stream neurons show evident responsiveness to stimulus features supposed to be encoded in the ventral stream, such as shape and color; likewise, some prototypical dorsal-stream features such as motion were shown to be equally well processed in the ventral stream (see Cardoso-Leite and Gorea 2010). The differential perceptual-motor effects caused by visual illusions have been criticized due to the unmatched experimental conditions used to assess them (Franz 2001; Franz and Gegenfurtner 2008). The differential effects of “invisible” primes have been questioned because “invisibility” was poorly defined and/or assessed or because the prime affects the perception of the target stimulus meant to trigger the motor response (Reingold and Merikle 1990; Holender and Duscherer 2004; Cardoso-Leite and Gorea 2010). Finally, results contrasting perceptual and motor response latencies and accuracies were undermined by the observation that such performance differences can be accounted for by a unique processing pathway, if perceptual and motor processes are assumed to require different levels of evidence to trigger a decision (Gibbon and Rutschmann 1969; see Cardoso-Leite and Gorea 2010).

A False Dilemma?

The ultimate consequence of the dual-pathway theory is that *perception* can direct action *unconsciously*, that is, that one can act appropriately on objects that are not seen. This proposition is theoretically debatable, but its test is empirically intractable. On the theoretical side, it makes use of undefined or ill-defined concepts, namely, “perception,” “not seen,” and “consciousness.” While it is unanimously accepted that the retina will transform light into an electrical signal, the stage at which its propagation becomes “perception” has been under sustained debate since the nineteenth century (see Boring 1942). According to

signal detection theory (Green and Swets 1966), a stimulus is reported as “unseen” either because it is too weak to elicit a neural response or because the subject adopts a high decision criterion, that is, because he or she requires more (neural) evidence of its existence than actually provided by the neural system. The absence of “consciousness” can be related not only to either of these two causes but also to a variety of ambiguous interpretations of this concept.

On pure common sense grounds, it would be ludicrous to contest the patently obvious dissociation between perception and action. However, the claim that when tested under *strictly matched conditions*, subjects’ action system may use incoming information that is omitted by the sensory systems may forever remain undecided for at least three reasons. First, because it is impossible to objectify a percept without requiring subjects to perform a perceptual judgment that ultimately involves some sort of action. As a consequence, one cannot prevent an action from interfering with its perceptual cause, and vice versa. For example, asking subjects to react as rapidly as possible in response to a sensory stimulus will lead to perceptual judgment errors (as evidenced by the motor response) that do not occur with a non-speeded motor response. Second, because in the absence of a clear-cut definition of consciousness, the distinction between conscious and unconscious perceptual states will remain elusive, making it hard to determine what sensory information is “omitted” (or not) by the sensory systems. Finally, even if such frontiers between action and perception and between conscious and unconscious states are arbitrarily set, *strictly matched conditions* for testing perceptual and motor performances cannot be created. For example, the putative “dissociation” between accurately grasping an object and this object’s perceptually distorted size by a visual illusion may be accounted for by positing that grasping control is based on the absolute spatial location of the grasping points, whereas perceptual size judgments are based on an estimation of the distance between these grasping points. Also, the finger grip aperture varies during the course of action as it is regulated by an online correction through visual

feedback, whereas a perceptual judgment is made once and for all.

Peripheral Nerve Interface Applications, Cochlear Implants

Robert V. Shannon
Department of Otolaryngology, University of Southern California, Los Angeles, CA, USA

Definition

A cochlear implant is an implanted electronic device to activate the auditory nerve and restore hearing sensations to people who have lost their hearing. Modern cochlear implants consist of an implanted part and a part that is worn externally. The external part contains a microphone to pick up sound, a microprocessor to convert acoustic sound into electric signals, and a transmitter coil

to send the information across the skin to the implanted part. The implanted part contains a receiving antenna, a microprocessor to decode the transmitted signal, a current-controlled stimulator, and an array of electrodes inserted into the inner ear. Electric pulses delivered to the inner ear activate any remaining auditory neurons and initiate neural pulses to the brain, resulting in the sensation of sound and the ability to understand speech.

Detailed Description

History

The normal inner ear separates sounds into its constituent frequencies and distributes the different frequencies along the coils of the cochlear (inner ear). High-pitch sounds produce vibrations predominantly at the entry to the cochlea (base), and low-pitch sounds produce vibrations predominantly at the tip of the cochlea (apex). Those vibrations are carried by a membrane (basilar membrane), and small ciliated cells called hair cells sit on top of the vibrating basilar membrane. The tiny cilia at the top of these cells are displaced at the place of maximum vibration and activate auditory neurons that synapse on these cells. This starts the cascade of neural firing patterns that signal sound to the brain. However, in most types of deafness, these hair cells are missing

from disease, drugs, noise exposure, or genetics. When the hair cells are missing, the mechanical vibrations still occur and the neurons are still present, but there is no connection between them, resulting in deafness. The cochlear implant is designed to inject electric current pulses into the cochlea to activate the nerve directly, bypassing the missing hair cells.

Electric activation of hearing may have originated with Alessandro Volta, who placed a charged glass rod in his ear and reported a sound like thick boiling soup. Electric stimulation as a modern prosthesis started in the early 1950s with André Djourno and Charles Eyries, a surgeon and an engineer, in Paris. They placed copper wires into the auditory nerve in two deaf patients and activated it by an inductive coil. The patients heard sounds and found it to be helpful with lip reading for several months before the device failed (Eisen 2003).

In the 1960s several groups developed implants for the cochlea to provide hearing sensations to deaf patients. One of the most successful of these was William House in Los Angeles (House and Urban 1973), who developed the first commercially successful cochlear implant. Most early implants were single-channel devices that consisted of a single pair of wires (source and sink) that passed electric current across the auditory nerve. These devices were enthusiastically accepted by deaf patients, who received the sensation of sound and could distinguish environmental sounds based on their different sound patterns. The single-channel implant provided little speech recognition by itself but greatly aided lip reading and so enhanced face-to-face communication and relieved the isolation felt by many deaf people.

Modern Development

Because early cochlear implants used only a single channel of stimulation, it could not activate the different pitch regions distributed along the cochlear. Multichannel electrodes were designed to activate multiple pitch regions. Typically a linear array of electrodes was placed along a carrier tube, and this assembly was inserted into the scala tympani, one of the three chambers of the

cochlea. Following such an insertion electric pulses stimulating electrodes at the basal end of the cochlea elicited high-pitch sensations, and progressively lower-pitch sensations were evoked each successive electrode going toward the cochlear apex. Modern cochlear implants have between 12 and 22 electrodes spaced along the pitch dimension of the cochlea. Low-frequency information is presented to the electrode at the tip of the electrode in the cochlear apex, and higher frequencies are presented to each successive electrode toward the base, so that the most basal electrode carries the highest-pitch information.

Evolution of Speech Processing

Early cochlear implants tried many different strategies for processing speech information. The problem was how to break up speech information and present it to the implanted electrodes to maximize speech understanding. With the original single-channel CIs, recipients heard sounds but mostly could not understand speech. They could hear environmental sounds and could tell the difference between some sounds by their overall rhythm – like the regular pulsing of a telephone ring versus the steady sound of running water. After time some were able to identify some sounds that had distinctive patterns and could recognize a few familiar words. Multichannel CIs allowed the recognition of words and some sentences. In the 1980s CI designers thought that they needed to extract the most important information from speech and just present that to the implanted electrodes. It was thought that the full speech information would overwhelm and confuse implant listeners. However, in the early 1990s, it was realized that the best CI performance was achieved when the designers “got out of the way.” A new generation of implant speech processors simply filtered sound into 22 bands of different frequencies and presented a form of the raw information to the 22 electrodes. There was a dramatic improvement in implant performance when speech-processing strategies allowed the listener’s own brain to extract the important information for itself rather than having an algorithm doing it. Small improvements in this strategy resulted in continued improvements in the

function of cochlear implants until the early 2000s, when most post-lingually deafened adult patients were able to understand speech well enough to have a conversation over the telephone. On standard evaluations the average CI adult was able to recognize 80–90% of the words in simple sentences presented in quiet. While speech recognition is excellent with modern cochlear implants, patients still have problems when listening in noise and listening to music. Many patients are now receiving bilateral CIs to allow localization of sound in space and better hearing in noisy conditions.

Children with Cochlear Implants

William House implanted the first deaf child with a single-channel cochlear implant in 1980. Most researchers at the time thought that this was highly premature, but acceptance by patients and families was good. Now more than half of worldwide cochlear implants are done in young children. While the auditory information from a cochlear implant is crude compared to a normal ear, it has proven to be sufficient for deaf children to develop speech and language in an almost normal fashion. Many children with modern cochlear implants can attend normal schools with only minimal help. One interesting aspect of this success is for neuroscience – it shows that pattern recognition of the brain for speech is robust enough to develop even with a highly reduced signal coming from the cochlear implant. In this case the brain is receiving patterns of information that are greatly reduced from a normal ear but can learn to understand and reproduce speech at a high level. Cochlear implants are now routinely done in congenitally deaf children less than one year of age.

Future Directions

One factor that limits the performance of cochlear implants is the distance between electrodes and neurons. The electric signal spreads out in the conductive body fluid and allows interference between adjacent electrodes. New electrode designs, including some that will be injected into the hearing nerve directly, are

being developed to improve the selectivity and independence of each electrode. It is the hope that more electrodes with high selectivity will allow the transmission of harmonic pitch and improved access to music.

New implant technology may allow the entire cochlear implant to be implanted under the skin, eliminating the external microphone and signal processor. This will improve the cosmetic appearance and allow the implant to be used even under water. An internal battery would be charged overnight.

Definitions

The electromyogram (EMG) is a record of electrical activity of muscles. Electrical activity in muscle arises from action potentials in muscle fibers. To record muscle electrical activity, small electrodes are placed on the skin over a muscle (surface EMG) or in the muscle (intramuscular EMG). The patterns of electrical activity can be displayed on a screen, played over a loudspeaker, stored to disk, and/or used as a control signal for a prosthesis or other device. EMG activity has been used as an approximate measure of the level of activation of the muscle or of muscle force.

The electroneurogram (ENG) is a recording of electrical activity from one or more neurons and typically refers to recordings made from bundles of axons in peripheral nerves. As with EMG, the recorded activity can be displayed on a screen, played over a loudspeaker, stored to disk, and/or used as a control signal for a prosthesis or other device. An ENG is obtained by placing an electrode in or near neurons to reveal activity of a single neuron or multiple neurons, depending upon the size and location of the recording electrode with respect to the neurons.

Detailed Description

Background

EMG is a measure of electrical activity in any of the three types of muscle tissue – smooth, cardiac, or skeletal (striated). Smooth muscle activation is controlled by the autonomic nervous system, hormones (e.g., Angiotensin II, Endothelin, and Epinephrine), metabolic factors (e.g., adenosine, CO₂, O₂), physical factors (e.g., via stretch receptors), and/or activity in neighboring cells. Smooth muscles can also be spontaneously active. Contractions in cardiac muscle fibers are initiated by electrical activity in neighboring cells or by endogenous currents that endow the cells with pacemaker properties. Striated muscles are activated by action potential generated by motor neurons of the spinal cord. The action potentials arrive at the neuromuscular junction and cause synaptic release of acetylcholine (ACh). ACh

causes local depolarization of the motor end plate generating action potentials in muscle fibers. The muscle action potential propagates along the muscle fiber and causes the release of Ca⁺² from stores within the muscle, which then leads to a contraction via a mechanism known as excitation-contraction coupling (Sandow 1952). In striated muscle, the release of Ca⁺² triggers a cascade of reactions that produces relative movement of the actin and myosin filaments, which generates a contraction of the muscle fiber (Merletti and Parker 2004). A typical muscle fiber membrane potential is about −90 mV and is more negative than that of a typical motor neuron. The muscle action potential lasts for about 2–5 ms with an absolute refractory period of 1–3 ms. The conduction velocity along a striated muscle fiber is about 4–6 m/s. An EMG recording consists of weighted summation of the depolarization waves that propagate through a muscle whether it is smooth, cardiac, or striated. Measured EMG potentials can range from less than 50 μV to 30 mV, depending on the muscle type, electrode type, and electrode location (Merletti and Parker 2004).

In 1849, the first recording of striated muscle electrical activity was done by Reymond (Du Bois-Reymond 1848). In 1890, Marey (1890) also recorded electrical activity from striated muscle and coined the term electromyography. However, it was not until the late 1930s and early 1940s that EMG found its first clinical uses (Denny-Brown and Pennybacker 1938; Golseth 1950; Weddell et al. 1943). As a clinical diagnostic tool, EMG is used in the diagnosis of neurological disorders (e.g., stroke (Bradley et al. 1998; Johnson et al. 1975), amyotrophic lateral sclerosis (ALS) (de Carvalho et al. 2008; Mitsumoto 1997), neuromuscular deficiencies (e.g., muscular dystrophy (Bushby et al. 2010)), movement disorders, and biomechanical problems (Kimura 2013; Preston and Shapiro 2013). Other applications of EMG are in biofeedback training as a method for rehabilitative physical therapy (Brucker and Bulaeva 1996), human-machine interfaces (Alsayegh 2000), ergonomic assessment (Kumar and Mital 1996), and in gaming technologies (Krepki et al. 2007). Furthermore, EMG has been used in control of

prostheses and orthoses for over five decades (Herberts et al. 1973; Kuiken et al. 2009; Scott 1967; Tenore et al. 2007) and in orthotics (DiCicco et al. 2004; Scott 1967). In research, EMG is used to assess motor control and learning, in the study of neuromuscular physiology, and in gait and postural analysis (Winter 2009).

ENG provides a direct measure of bioelectrical activity in neurons arising from the movement of ions across the cell membrane. The movement of ions is driven primarily by concentration gradients and is regulated by the opening and closing of channels. The action potential consists of an influx of Na^+ , Ca^{2+} , and/or Cl and an efflux of K^+ (Kandel et al. 2000). With electrodes placed near or in neural tissue, one can measure the tissue electrical activity. Electroneurograms can be obtained by recording neural activity with electrodes inserted in the soma of neurons (intracellular) or with electrodes positioned in the medium surrounding neurons (extracellular). In the peripheral nervous system, ENG can be obtained by recording extracellular action potentials from neurons in the peripheral ganglia or from axons of peripheral nerve bundles. Depending on the design and placement of the electrodes used to record neural activity, an ENG can contain activity of a single neuron or the superposition of signals from many active axons in a nerve.

The first ENG from a single nerve fiber was recorded by Edgar Adrian in 1928 using a Lippmann electrometer (Adrian 1928). In 1953, the first Iridium recording microelectrode was developed (Dowben and Rose 1953). The first simultaneous recording from multiple units with a multielectrode array from a patient during brain surgery was published by Marg and Adams in 1967 (Marg and Adams 1967). In the peripheral nervous system, ENG is used for many purposes: as a diagnostic tool for the assessment of motor disorders (Hoffmann and Krechel 2011) (e.g., ALS (Lei et al. 2002), multiple sclerosis (MS) (Nesrulaeva et al. 2011)), in biofeedback (e.g., for closed loop systems in stimulation of end organs and muscles and in control of orthotics and prostheses (Dhillon et al. 2004; Micera et al. 2010; Navarro et al. 2005)).

Acquisition and Presentation

There are two primary types of EMG recordings: surface EMGs (sEMG) and intramuscular EMGs (iEMG). sEMG recording electrodes are placed on the skin over a muscle of interest. Electrodes for sEMG are typically made of Ag-AgCl and attached to the skin with an adhesive collar. These EMG electrodes detect EMG signal through the skin using a conductive gel between the electrode and the skin. Dry sEMG electrodes are made of stainless steel and other alloys. The electrodes detection surface depends on the type of material used, but for Ag-AgCl it is at a range between 0.5 and 1.5 cm. sEMG electrodes are either placed in the unipolar, bipolar, or even quadpolar configuration. In a unipolar configuration, the EMG is recorded from a single electrode placed on the muscle with the reference ground electrode placed in an electrically neutral location, e.g., near a bony prominence. Bipolar EMG recording requires two electrodes placed next to each other along the longitudinal axis of the muscle in the direction of the depolarization current propagation. The inter-electrode separation for bipolar recording is between 0.25 and 1.5 cm. sEMG electrodes are not specific; they record signal from a large set of active motor units that produce the overall contraction of a muscle. Unipolar sEMG electrodes detect neural activity from a larger area of muscle tissue than bipolar sEMG electrodes. However, bipolar electrodes are the most common recording configuration used since they provide a high signal-to-noise ratio. Additional information on surface EMG recording can be found in the following references: Criswell (2010) and Kasman and Wolf (2002). iEMG recording electrodes are placed in the muscles. Intramuscular electrodes are selective in that they record action potentials from a small number of motor units depending on the electrode geometry and placement. iEMG can also be used to provide recordings from deep muscles not accessible to surface electrodes. Intramuscular electrodes come in many different designs: simple single filament needle, concentric single filament, bifilar, quadfilar, and macro-electrode (Trontelj et al. 2004). Implantable EMG sensor systems

have also been developed that have the ability to wirelessly transmit signals to an external receiver (Weir et al. 2009).

Recorded EMG signals are the sum of many trains of action potentials from many motor units plus sources of noise present in the environment including the recording apparatus. The contribution of each motor unit to the recorded EMG will depend upon the fiber size (larger fibers generate larger signals) and the distance from the recording electrode (the signal produced by the fiber will attenuate as it passes through the resistive medium). EMG signal frequencies range from 1 Hz to few kHz with amplitudes from few μV to mV (Reaz et al. 2006). A good EMG recording requires good electrode design, electrode placement near muscle depolarization sources, sound recording amplifier design, grounding techniques, and noise reduction methods (Fridlund and Cacioppo 1986).

The EMG recording system amplifies and conditions the EMG signals. Typical recording systems are equipped with low noise, high common mode rejection ratio (CMRR >90 dB), and high input impedance ($\text{M}\Omega$ – $\text{G}\Omega$) differential amplifiers with high bandwidth (0.1–5 kHz) that amplify the EMG signal acquired by electrodes. The amplified signals are then passed through a sequence of high-pass (0.1–100 Hz), low-pass (500–1000 Hz), and notch (60 Hz) filters to remove contaminants of the EMG signal, such as movement artifacts and power line noise. The amplified, conditioned EMG signals can then be digitized by analog-to-digital converters (8–16 bit) and then processed, stored, and/or displayed (De Luca 1979; Fridlund and Cacioppo 1986).

EMG signals can be displayed on an oscilloscope or on a computer screen as multiple traces where the ordinate (y-axis) represents the amplitude of the signal and the abscissa (x-axis) time. They can also be presented as audio signals. Another method to visualize EMG signals as a dynamic heat map where the color intensity represents the amplitude of the signal, the abscissa time, and the ordinate the channels.

ENG signals are at least an order of magnitude lower in amplitude and higher in frequency than EMG signals. To record ENG, many neural

machine interfaces (NMI) have been developed. Some NMIs are selective recording devices, recording only from few neurons/axons while others are designed to record from many sources. However, with higher selectivity comes increased level of invasiveness (Navarro et al. 2005). To achieve selectivity, electrodes must be placed closer to axons or neuron cell bodies and thus are more invasive than electrodes that are placed distant from neural sources. The cuff electrode is a peripheral neural interface. It is a tubular sheath with two or more recording contacts on its inner surface connected to lead wires (Testerman 1982). Cuffs are placed around nerves and record a sum of neural activity from many axons. The flat interface nerve electrode (FINE) is a variant of the multi-contact cuff that is designed to achieve better recording selectivity by flattening the nerve to distribute fascicles across the array of contacts (Tyler and Durand 2002). Penetrating microelectrodes (PME) are inserted in a fascicle of a peripheral nerve. PMEs are used in microneurography to measure multiunit peripheral nerve activity to investigate peripheral nervous system physiology and pathophysiology (Nystrom and Hagbarth 1981; Vallbo et al. 1979). Longitudinal intrafascicular electrodes (LIFEs) are made of a thin (25–100 μm) Pt-Ir insulated wire with 1–2 mm exposed active site (Malagodi et al. 1989). LIFEs offer high selectivity because they interface with a subset of axons within a fascicle of a peripheral nerve. The thin-film LIFE (tfLIFE) is a flexible micromachined polymer structure with multiple active contacts that are smaller in surface area than those of the LIFE (Yoshida et al. 2000). The multielectrode array (MEA) is an array of needle electrodes; these can be made of stainless steel, tungsten, or conductive silicon. Several variants of microwire MEAs use an array of single-contact electrodes made of stainless steel or tungsten and are usually arranged in a two-dimensional grid to access spatially distributed sets of fibers. Conductive silicon has been used to put multiple contacts on a single probe in the Michigan probe (Suner et al. 2005) and to create a high-density array with 100 contacts in the Utah array (Campbell et al. 1993). If designed with appropriate dimensions, these MEAs can achieve

simultaneous recordings from multiple fascicles. Regenerative electrodes are a large array of pores or conduits in which axons could regenerate (Akin et al. 1994; Devor and Govrinlippmann 1979; Kovacs et al. 1992). A recording electrode is placed in each pore in order to record from the small group of axons that may grow through the pore as it regenerates toward the target organ.

As with EMG, the recorded ENG signal consists of the superposition of signals emanating from many individual neurons and several noise sources. The contribution of a given neuron is influenced by the neuron fiber type and location: size and proximity to the electrode both increase the amplitude of the recorded signal. With any ENG electrode, the specific features of the ENG recorded signals are also influenced by the size and shape of the active contact (i.e., recording surface), and placement of the electrode determines recording volume shape and size (i.e., pickup distance around the electrode). Finally, the recording configuration (unipolar, shared reference, bipolar recording, tetrad recording, etc.) also influences the information content of ENG. The amplitude of the recorded neural activity usually lies between 1 and 100 μV , and the frequency content ranges from few Hz to 10 kHz, depending on whether the signals recorded are single spikes, a superposition of many spikes (e.g., compound action potentials), or local field potentials (LFP).

ENG must be amplified and conditioned prior to processing and/or analysis. A neural recording system typically includes an initial amplifier stage and a signal conditioning stage to attenuate energy in specific frequency bands. The structure of the ENG recording system is similar to that of an EMG recording system. The initial neural signal amplifier usually requires a low referred noise ($<2\mu\text{Vpp}$), high common mode rejection ratio (CMRR >90 dB), high input impedance ($\text{M}\Omega$ for low impedance electrodes and $\text{G}\Omega$ for high impedance electrode), and high-gain (1000–500,000) differential recording capability with high bandwidth (0.01–10 kHz). Amplifiers are followed by a set of filters (signal conditioning stage) in sequence, consisting of high pass (0.01–1000 Hz), low pass (500–10,000 Hz), and notch (50 or 60 Hz) to

remove contaminants of the ENG signal, such as, EMG noise, neural tissue background noise, movement artifacts, and power line noise. The amplified, conditioned ENG signals are usually digitized by analog-to-digital converters (16–18bits) and either stored or transferred to a computing machine for further analysis and/or display.

The rich information content in multichannel, high-bandwidth ENG recordings can be extracted using various analysis methods or by displaying the information in a useful manner. Individual traces representing the time series of multiple channels can be vertically stacked to simultaneously provide visual information regarding single-channel dynamics and patterns across channels. However, this kind of representation is limited in its ability to convey information content that spans multiple time scales and has complex spatial patterns. An alternative is to use dynamic heat maps where channels are represented as ribbons unfolding in time with the color intensity at the current time representing the signals strength. A precursor to dynamic heat maps are raster plots for spike event data visualization (Drongelen 2007). Yet another method of representation is raster plot put in a form of a tunnel view (Walter et al. 2004) in which the trains of spikes are clustered dynamically in a way to represent the correlation between data events.

Analysis Methods

Raw EMG and ENG signals contain valuable information, but extracting that information from the set of recordings usually requires online or off-line signal processing and/or machine learning methods (Reaz et al. 2006). Signal processing methods include frequency domain, time domain, or mixed mode methods. For example, frequency domain methods include Laplace, Fourier, and Z transforms, power spectral density, and signal phase calculations, while time domain methods include time series analysis (moving averages and higher moments, cross-auto/correlations, convolutions, etc.). Mixed mode methods are methods such as band-pass filters, spike rate calculations, wavelet analysis, short Fourier

transforms, etc. Machine learning procedures are algorithms used to uncover statistical regularities in data. They involve learning information from previous data and generalization to new data (i.e., prediction). Some of the most common methods of machine learning used in EMG/ENG processing are principal component analysis (PCA), independent component analysis (ICA), support vector machines (SVM), and artificial neural networks (ANN) (Drongelen 2007; Hinton 2011; Lewicki 1998).

EMG/ENG processing often utilizes a sequence of steps designed to remove noise and to find temporal and spatial (multiple channels) regularities in signals. Linear/nonlinear filtering techniques are used to remove noise from the signals. For example, one useful measure of activity on a recorded channel is spike frequency: either instantaneous spike frequency or spike frequency calculated over a time window. For this calculation, simple thresholding or a Schmitt trigger can be used to detect spike events in noisy signals. These techniques require the selection of a threshold value, which is often selected as a multiple of the recorded quiescent activity (e.g., three times the standard deviation of the signal recorded with the subject at rest). Wavelet denoising (Moshou and Hostens 2000) and Wiener filters (Aschero and Gizdulich 2010) can also be used to remove noise from ENG/EMG. A matched filter approach can sometimes be used if muscle action potentials or neural spike information are available a priori (Drongelen 2007; Lewicki 1998) to filter iEMG/ENG spikes from noise.

Since EMG is a sum of the activity of many motor units and likewise ENG is a sum of many neuronal action potentials from a number of neurons, further processing might be needed to decompose the EMG/ENG to its contributing sources. For some applications, separating the biological sources is necessary. Decomposing EMG/ENG to its constituent components relies on the assumption that each source action potential (spike) has a distinct shape and temporal characteristic. To achieve this decomposition, many algorithms have been developed. These algorithms are of two basic types: spike

identification or classification and decomposition, known also as sorting. After band-pass filtering in the frequency range of interest of EMG/ENG data to accentuate spikes, detected spikes are superimposed on top of each other, a method known as alignment, to detect and extract identifiable features of the spike. These features are later used to reprocess EMG/ENG data. After spike identification, EMG/ENG signals are decomposed to their primary constituents using a variety of methods some of which are template matching and convolution filtering (Lewicki 1998). Another related method used for decomposition of EMG/ENG signals is known as wavelet decomposition, which relies on the use of templates of generic spikes (wavelets), such as Symlet and Daubechies wavelets, to sort neural or muscle sources (Reaz et al. 2006). Often EMG/ENG signals have a low-frequency (<50 Hz) modulation of interest. There are many signal processing methods that have been used to extract the modulating signal from EMG/ENG recording. They are all essentially low-pass filtering techniques. Some examples are root mean square (RMS) of the signal or signal absolute value (AV) over a moving window, Gaussian filtering (Lehky 2010), Kaiser filtering (Massot et al. 2012), etc.

The processing methods presented above only allow analysis of the temporal or frequency characteristics of individual EMG/ENG signals. Pattern classification or machine learning methods can be used to analyze the spatial patterns across a group of signals. Either supervised or unsupervised classification (regression models) (Hinton 2011) can be used. Unsupervised models such as independent component analysis or principal component analysis can recover essential components of EMG/ENGs by removing correlated channels and keeping only independent sources. In supervised methods, such as support vector machines and artificial neural networks, the input EMG/ENGs are correlated to some behavioral signals such as the movement of an arm, visual signal, or movement of a cursor on screen, which are deemed related to the EMG/ENG signals. These methods are used in an attempt to remove all components that are not related to intended behavior from the ENG/EMG data

(Abdelghani et al. 2013a, b; Bitzer and van der Smagt 2006; Micera et al. 2010; Sinkjaer et al. 2003).

This list of analysis methods presented is only a few of many processing techniques that have been used to analyze EMG/ENG data. A detailed review of EMG analysis is given by Reaz et al. (2006) and of ENG analysis is given by Van Drongelen (2007).

Computational Models

Computational modeling and simulations of EMG/ENG signals is particularly interesting for developing new EMG/ENG analytical tools. Simulation enables testing of scenarios that are not feasible in limited and controlled experimental settings. Furthermore, it enables the formulation of prediction that can be tested with a targeted experimental protocol. Lee et al. (2008) have produced a volume conductor model to simulate surface EMG due to current sources located at different depths of muscle tissue. With their method, they studied EMG electrode configuration and spacing. Stalberg et al. (Stalberg and Karlsson 2001) simulated an EMG from a muscle with its motor unit as it was picked up by concentric needle electrodes under pathological situations such as myopathy. Li et al. (2013) used simulated EMG data to compare the performance of several multichannel EMG decomposition algorithms. ENG simulation is also a rich area of study with many mathematical and simulation software packages published (Bower and Beeman 1998; Brette et al. 2007; Gewaltig and Diesmann 2007; Hines and Carnevale 1997). An example is the simulation of neural signals recorded by multiple longitudinal fascicular electrodes implanted in peripheral nerves for the purpose of testing neural decoders to control advanced prostheses (Abdelghani et al. 2013a, b).

Peripheral Nerve Interface Applications, Neuropathic Pain

Narendra Bhadra

Neural Engineering Center, Department of Biomedical Engineering, Case Western Reserve University, Cleveland, OH, USA

Synonyms

Nerve pain; Neuralgia; Neurodynia

Definition

Neuropathic pain (NP) is a direct consequence of lesions or disease affecting the central or peripheral somatosensory system. Peripheral nerve interfaces are systems for delivery of therapeutic modalities directly to the peripheral nervous system, such as the management of NP.

Detailed Description

Pain is a subjective feeling of physical suffering and discomfort from the sensory modality of nociception (pain perception) by activation of terminal receptors. A direct activation of pain pathways can also result in the perception of pain without extrinsic activation of end receptors. Such “neuropathic pain” may be caused by disease or injury. The International Association for the Study of Pain (IASP) defined NP as “pain caused by a lesion or disease of the somatosensory system” (IASP 2011; Jensen et al. 2011).

Patients with NP may have reduced sensation to touch and temperature in affected areas (negative signs and symptoms). They may have spontaneous non-painful sensations (paresthesias), with episodes of shooting or burning pain. They may also have pain evoked by usually non-painful mechanical or thermal stimuli (hyperalgesia).

Electrical peripheral nerve stimulation (PNS) can be of therapeutic use in the management of NP (Slavin 2008; Stanton-Hicks 2009). Soon after the “gate control” theory of pain was proposed by Melzack and Wall in 1965, Wall and Sweet demonstrated the effects of peripheral nerve stimulation on pain perception (Wall and Sweet 1967). There followed a number of publications on PNS for NP (Nashold et al. 1979; Waisbrod et al. 1985). In the ensuing decades, peripheral nerve stimulation for NP has gained wider clinical application (Gildenberg 2006; Slavin 2011a).

Pathomechanics of Neuropathic Pain

NP can arise in a variety of clinical conditions such as diabetes, trauma, or autoimmune disease (Campbell and Meyer 2006). Pathology has been attributed to the abnormal sensitization of nociceptors with ensuing changes in spinal dorsal horn neurons and altered C-fiber activity. Central neurons in the thalamus and primary sensory cortex may also be sensitized. Following localized nerve injuries, inflammation may also play a role in NP (Nickel et al. 2012). Changes in the expression of sodium channel isoforms have been implicated in NP (Lai et al. 2003; Rogers et al. 2006).

Peripheral Nerve Stimulation for Neuropathic Pain

PNS has been applied to a number of peripheral nerves to treat a variety of conditions such as migraine, occipital neuralgia, and postherpetic pain. Peripheral sensory nerves supply demarcated areas of skin surface, which may show altered sensibility in NP. Such nerves are targets of PNS for therapy as in the periorbital and inguinal areas. Regional anesthetic nerve block has not been definitely shown to have any predictive value in the efficacy of PNS for NP (Slavin 2008).

Nerve Interfaces for Neuropathic Pain

The electrode interface is the transition plane from current flow by electrons in the technological

Peripheral Nerve Interface Applications, Neuropathic Pain, Fig. 1 (a) Percutaneous lead electrode with four contacts, with connecting lead wire on the

left, (b) paddle-type electrode with four contacts, and (c) cuff electrode with three contacts

hardware to ionic currents in physiological media. Electrodes may be noninvasive to provide stimulation through the skin surface or implanted on or near the nerve. The metal electrode contact at the interface is connected to an electrical pulse generator, external for surface and percutaneous systems or implantable (IPG).

(Navarro et al. 2005). They may also provide selective activation of target nerves without spill-over currents, with established safety records for some designs (Naples et al. 1988). Cuff electrodes have been used for phantom limb pain in amputation stumps for kHz frequency nerve block (Soin 2012). They are not widely used for PNS in NP.

Implanted Systems

Percutaneous leads are the most commonly used and can be inserted through the skin to be seated near a target nerve (Fig. 1). The cylindrical electrodes have linear arrays of 4–8 ring-shaped metal contacts that transfer electrical charge to the target nerve.

Flat paddle-shaped electrodes, with metal contact interfaces on one surface, backed by insulating material have been used since the late 1980s (Slavin 2011b). These electrodes are manufactured by a number of companies with 4, 8, or 16 electrode contacts.

Nerve cuff electrodes with cylindrical geometry can wrap around the trunk of peripheral nerves and may conform to their shape. The electrical interface is positioned close to neural tissue, which can lower the threshold currents and decrease the power demands of stimulators

Peripheral Nerve Interface Applications, Obesity

Mitchell Roslin and Andrew Brownlee
Lenox Hill Hospital/NSLIJ, New York, NY, USA

Definition

The peripheral nervous system interfaces with multiple organs and mediates a myriad of biochemical processes that affect the balance of

energy storage and consumption. This interface has long been studied as a target to alter the balance of weight homeostasis.

Detailed Description

Health issues arising from the increasing prevalence of obesity and metabolic syndrome are becoming a global predicament. For the first time, more people will expire secondary to issues from weight excess than famine.

Weight homeostasis is based on the simple balance between energy intake and energy expenditure. Obesity, or excess accumulation of fat, occurs if there is an imbalance. The interaction between the gastrointestinal tract, the brain, and the autonomic nervous system controls and modulates energy homeostasis. As a result, electronic manipulation of each of these components can potentially alter signals and change dietary intake and metabolic rate. In fact, electrical stimulation or blockade using pacemaker technology has been placed on the stomach, the vagus nerve, the sympathetic nerves, and directly into the hypothalamus in experimental trials to treat obesity.

The sympathetic and parasympathetic nervous systems, which arise from the spinal cord, supply the vital organs and affect their function. Activation of these nerves is often part of a reflex mechanism which involves the efferent signal with an afferent limb which relays signals back to the CNS and often to the hypothalamus. The hypothalamus also has connections to higher brain centers and therefore is paramount in the regulation of metabolism (Van Baak 2001).

Overall, increased activity of the SNS results in decreased energy uptake with increased energy expenditure. Conversely, PSNS activity results in increased energy uptake and decreased energy consumption. Obesity is a product of energy intake exceeding energy expenditure and can be caused by an imbalance at any level of this complex system (Van Baak 2001).

The word vagus actually means wanderer in Latin. It is the interstate highway that connects the brainstem to our vital systems controlling our heart rate, breathing, and gastrointestinal tract. For

surgeons, the vagus nerve is best known for its function in acid production, motility, and pancreatic secretion. This effect constitutes part of the efferent limb of the vagus nerve. Theoretically, it has been suggested that if efferent vagal activity is blocked, then gastric emptying would be delayed. This would result in increased satiety and reduced hunger. Additionally, blocking pancreatic activity would cause reduced or inefficient digestion of ingested food. Two randomized controlled trials (EnteroMedics) have been completed utilizing a pacemaker with thresholds that block vagal efferent signals (Waataja et al. 2011). Both studies failed to show a significant difference in weight loss in the experimental group. They did, however, show a tendency that patients treated were more likely to lose weight and further refinement with better patient selection may allow for clinical application.

The afferent sensory limb interestingly constitutes 80% of the function of the nerve, and distension of the stomach results in a powerful neuronal signal relaying satiety to the brain both directly and via the hormones. Cholecystokinin (CCK) and ghrelin, two powerful hormones involved in hunger, activate vagal afferent pathways (Van Baak 2001). Thus it would be reasonable to stimulate vagal afferents attempting to mimic satiety or fullness. Trials with both direct vagus nerve stimulation and indirect vagus nerve stimulation with leads on the stomach have been attempted. Roslin et al. showed impressive weight loss in a canine model treated with bilateral vagus nerve stimulation. A brief six-patient clinical trial was not able to replicate these results (Roslin and Kurian 2001). Direct gastric stimulation (Transneuronix) underwent two multicenter randomized trials in the United States after numerous nonrandomized trials suggesting efficacy. Neither controlled trial showed statistical significance (Cigaina 2004). Another method of indirect stimulation has been utilized by Metacure. A sensing pathway attempts to detect the intake of food, timing the pacing cycle.

Low SNS tone is associated with a low metabolic rate and hyperphagia. Low urinary adrenaline excretion (a marker of low SNS tone) has been shown to be associated with weight gain. The SNS stimulates thermogenesis and that dietary manipulation influences noradrenaline turnover (Van Baak). Conversely, sympathetic activation has

been associated with enhanced meal-induced satiety showing that the SNS has a dual effect, working on both sides of the energy balance equation. Stimulation of the sympathetic system to increase metabolic rate has been attempted. Leptos did animal efficacy trials with placement of abdominal leads (Dobak 2004). Several clinical cases were done in Europe without exciting or beneficial results. Therefore, the United States trial was cancelled.

Clearly, the wiring pathway is intact. There is little question that peripheral nerves are both an input channel and output conductor that regulate energy intake and utilization. However, how to manipulate these connections and the language to send the proper signal remain to be determined.

Diaphragm pacing; Phrenic nerve pacing; Respiratory electrical stimulation

Definition

Respiratory pacing is a technique that uses patterned repetitive electrical stimulation to activate ventilatory muscles in order to increase airflow in the lungs. Respiratory pacing is usually used in cases of cervical spinal cord injury (SCI) where the connection between the respiratory drive centers and the respiratory nerves has been lost, though other disorders may also be candidates. Pacing may be delivered by peripheral nerve stimulation (typically the phrenic nerve that innervates the diaphragm), intramuscular stimulation (typically the thoracic diaphragm), or spinal cord stimulation. Respiratory pacing is used as an alternative to mechanical ventilation which may cause trauma to the lungs and other respiratory and psychological complications.

Detailed Description

Background

Respiratory pacing provides a solution for individuals with chronic ventilatory insufficiency or those individuals with high-level spinal cord injuries where the brain can no longer drive the lungs enough to maintain gas exchange necessary for survival. Respiratory pacing is a technique to supply adequate ventilation to the lungs such that appropriate gas exchange (respiration) can occur. Respiratory pacing uses functional electrical stimulation (FES) to activate the muscles of ventilation. The diaphragm has been the primary target for respiratory pacing as it provides the majority of inspiratory activity. Early efforts in the 1940s and 1950s (Sarnoff et al. 1948, 1950) and later in the 1960s (Glenn et al. 1964) and 1970s (Glenn et al. 1976; Glenn 1978) focused on providing stimulation to the phrenic nerve in order to drive the diaphragm. In the 1980s, motor point stimulation of the diaphragm muscle was demonstrated (Nochomovitz et al. 1983, 1984, 1988; Peterson et al. 1986). Refinements in devices and laparoscopic surgery for motor point stimulation in the diaphragm followed (DiMarco et al. 2002; Onders et al. 2004a, b, 2005). Because of the importance of maintaining adequate ventilation, respiratory pacing has had continual scientific attention with

numerous publications, including a wealth of review articles on the topic (DiMarco 2005, 2009, 2018; Jarosz et al. 2012; Onders 2012; Le Pimpec-Barthes et al. 2016; Hachmann et al. 2017).

As the primary muscle of breathing, the thoracic diaphragm (innervated by the phrenic nerve, arising from cervical nerves 3–5) provides 65% of vital capacity (Jarosz et al. 2012). The external intercostal muscles assist in inspiration by increasing the size of the chest. Additional muscles in the neck and trunk provide small contributions to inspiration. Active expiration is typically not required during quiet breathing where expiration is primarily passive. During conditions such as exercise, expiration is assisted primarily by the internal intercostal muscles and the abdominal muscles, decreasing the size of the chest and abdominal cavities, respectively.

Ventilation is controlled by the autonomic nervous system, with limited voluntary control. Respiratory rhythm and pattern generation arises from neurons and neural circuits in the brainstem. At the heart of the respiratory control system is a central pattern generator (CPG). This CPG can functionally reconfigure during other behaviors such as coughing, swallowing, vocalization, and vomiting (Lindsey et al. 2012). Ventilatory rate is primarily controlled by blood levels of CO₂, with additional control based on blood levels of O₂ (Dean and Nattie 2010; Guyenet 2014; Guyenet and Bayliss 2015). Mechanoreceptors prevent over inflation of the lungs (Herring Brewer reflex (Schelegle 2003; Harris and St John 2003; Ahmed 2007; Leiter and Manning 2010)). The most common cause of loss of ventilation is cervical SCI. With SCI at the fifth cervical vertebrae or higher, the connection between the respiratory centers in the brainstem and the phrenic nerve is damaged. This loss of respiratory control necessitates the use of artificial ventilation including respiratory pacing. Other disorders which are candidates for respiratory pacing include congenital central hypoventilation syndrome (Diep et al. 2015; Kasi et al. 2016) and central sleep apnea (Ponikowski et al. 2012; Abraham et al. 2015). Amyotrophic lateral sclerosis (ALS) has also been evaluated as a target for respiratory pacing (Amirjani et al. 2012; Scherer and Bedlack

2012). However, a recent study showed evidence of increased number of adverse events in ALS patients with respiratory pacing compared to those with mechanical ventilation support (McDermott et al. 2015).

Stimulation Approaches

A number of different methods using FES for respiratory pacing have shown success. In all FES systems, some surviving neuromuscular tissue must remain. In the case of spinal cord injury, the spinal cord, motoneurons, and muscles distal to the injury typically remain intact. Stimulation of any of this intact tissue can activate otherwise paralyzed muscles to contract and cause functional movement. In order to get a useful contraction capable of evoking a breath, sufficient stimulation frequencies with sufficient charge delivery are needed. Slow motor units require 25–30 Hz while fast motor units require 80–100 Hz stimulation frequencies to allow fused contractions of the muscles (Wuerker et al. 1965; Venkatasubramanian et al. 2006). While open-loop (feed-forward) control systems for electrical stimulation are common (Jarosz et al. 2012), closed-loop (feedback) and adaptive controllers have the possibility of correcting for fatigue and electrode instability (Abbas and Triolo 1997). This is important as electrically stimulated muscles have time-varying, nonlinear properties, which complicate control (Crago et al. 1980a, b; Durfee and Palmer 1994). There are three major approaches for respiratory pacing: phrenic nerve stimulation, intramuscular stimulation, and spinal cord stimulation.

Phrenic nerve pacing was established as a clinical modality in the 1980s (Glenn et al. 1984). In this technique, electrodes are attached to the phrenic nerve in the neck or the thoracic cavity to increase diaphragm function. Most often extraneural electrodes like nerve cuffs are utilized although in the future it may be possible to use intraneural electrodes such as the longitudinal intrafascicular electrode (LIFE) (Venkatasubramanian et al. 2006). In current open-loop phrenic pacing systems, the electrodes are connected to an electrical impulse generator and stimulator implanted under the skin. This stimulator receives wireless commands from

an external transmitter. Phrenic pacing has successfully provided respiration for spinal cord injured individuals on a chronic basis without the need for mechanical ventilation. The electrodes are placed on the nerve after a cervical or thoracic surgical procedure. Historically, surgeries required very invasive bilateral thoracotomies (Onders 2012), but newer surgeries are typically performed thoracoscopically, decreasing surgical risk (Fodstad 1987; Vanderlinden et al. 1988; Shaul et al. 2002; Morgan et al. 2003). Commercially available devices for respiratory phrenic pacing include the Astrostim system from Atrotech in Finland, the Vienna phrenic pacemaker from Medimplant in Austria, and the Avery Mark IV Breathing Pacemaker System from Avery Biomedical Devices in the USA (only the Avery system is available in the USA) (Onders 2012).

Intramuscular respiratory pacing involves placing electrodes in the muscles of ventilation near the motor point, beneath the surface, of each muscle (Jarosz et al. 2012). Electrodes with leads that cross the skin are typically placed in the diaphragm, but can also be placed in secondary muscles such as the intercostals to further increase ventilation (DiMarco et al. 2005). These devices do not require the complicated surgeries needed for most phrenic stimulators. While surgery is still invasive, it can be done laparoscopically as outpatient surgery through the abdomen (Onders et al. 2004b). Commercially available devices include the NeuRx RA/4 System from Synapse Biomedical in the USA.

High frequency spinal cord stimulation is an emerging technique for respiratory pacing (DiMarco and Kowalski 2013; Kowalski et al. 2013; DiMarco et al. 2019). Electrodes are placed on the epidural surface of the upper thoracic spinal cord (T1-3). This technique results in asynchronous firing of phrenic motoneurons, which may lead to a more physiological activation than the synchronous firing seen in phrenic nerve and intramuscular stimulation. No commercially available devices are currently in production.

Recently, a new approach has been developed where a venous catheter equipped with

stimulating electrodes is inserted into the subclavian vein and used to stimulate the phrenic nerve through a transvenous approach (Abraham et al. 2015; Costanzo et al. 2016; Reynolds et al. 2017). This minimally invasive transvenous phrenic stimulation approach has been able to provide both unilateral and bilateral phrenic nerve stimulation in patients with central sleep apnea (Ponikowski et al. 2012; Abraham et al. 2015) and temporarily in patients undergoing cardiac surgery in an investigational study (Reynolds et al. 2017). Currently, only the *remedē* system from Respicardia has been approved for treatment of central sleep apnea in the USA.

Limitations and Alternatives

While breathing is an immediate need provided by mechanical or stimulated ventilation, coughing is an important behavior that is not always supported by pacing systems. Individuals with impaired ventilation have an increased risk of respiratory infections, particularly in the absence of cough (Zimmer et al. 2007). Cough is necessary for clearance of mucous and can also be necessary to prevent choking if food becomes lodged in the respiratory system. Simulated coughs can be performed using abdominal thrusts by an assistant and stimulation of the abdominal muscles or corresponding spinal motor pools (Jaeger et al. 1993; Lee et al. 2008; DiMarco et al. 2009; McCaughey et al. 2016).

While modern electrode design minimizes some risks, all methods of respiratory pacing have the risk of electrode failure. Electrode failure can arise in a number of ways: the electrode may move from its target location (exacerbated by significant tissue movement at the site), it may corrode over time (causing electrode damage as well as tissue toxicity), and it may suffer from mechanical failure of the circuit path (Venkatasubramanian et al. 2006). Pacing effectiveness may change over time. Fatigue is particularly important following respiratory muscle atrophy commonly seen following use of a mechanical ventilator. While in an uninjured system, motor units are physiologically recruited slow to fast, electrical stimulation typically

results in reverse recruitment, fast (fatigable) to slow. This leads to significant difficulties with graded recruitment and muscle fatigue. The amplitude of the stimulation also needs to be tuned as the muscles strengthen following prolonged use of respiratory pacing devices. Early implantation of pacing systems following injury will decrease the adaptation time as well as decrease the chance of respiratory illnesses (Onders 2012). As mechanical ventilation (always a bridge to pacing systems) typically involves hyperventilation of users, PCO₂ levels are reduced. As pacing systems are designed to provide normal ventilation, acidosis may arise as PCO₂ levels return to normal (Onders 2012). When pacing is extended to sleep, airway obstructions may occur and upper airways may collapse. Tracheostomy valve caps may be implemented to prevent collapse if it occurs (Onders 2012). Diseases such as chronic obstructive pulmonary disease which increases mucous production and reduces airflow in the respiratory system may also limit the effectiveness of respiratory pacing systems and relegate individuals to mechanical ventilation systems.

The primary alternative to respiratory pacing is mechanical ventilation. With mechanical ventilation devices, air is forced into the lungs with positive pressure. While very effective at providing airflow to the lungs, these devices have significant physiological and psychological complications. Speech, noise, social stigma, risk of infection, caregiver requirements are all additional negative factors of mechanical ventilator usage (DiMarco 1999). Finally, posterior lobe atelectasis, barotrauma, pneumonia, and other respiratory complications are the leading cause of death for SCI individuals on ventilators (Krause et al. 2004; Shavelle et al. 2006). In the case of individuals with SCI, depending on the degree of injury, exercise and pulmonary rehabilitation without the use of a ventilator or pacing system may be possible. However, as most individuals with respiratory insufficiency have limited motor control, they may be unable to perform the exercises typically prescribed for cases such as COPD without the use of ventilatory assist (Aboussouan 2009).

Definition

Sensory restoration is a process for providing information to the nervous system about either the external environment or internal body state, typically by replacing or augmenting sensory pathways that are dysfunctional as a result of disease or injury. Examples of pathways in the peripheral nervous system that might be targeted for sensory restoration include proprioception (i.e., limb position sense), cutaneous sensation (i.e., sense of touch), and internal organ state (e.g., bladder fullness). Sensory restoration is

typically achieved by recording from an electrical transducer and translating that recording into a set of electrical impulses which are delivered to peripheral nerves via a stimulating electrode. Sensory information is encoded by varying the amplitude, frequency, and anatomical location of the stimulating impulses.

Detailed Description

Sensory restoration is a process for replacing or augmenting damaged or dysfunctional afferent pathways in the nervous system to provide information about the external environment or internal body state. This process can be achieved by recording signals such as pressure, temperature, force, or position and encoding those signals into electrical impulses that are delivered to peripheral nerves by stimulating electrodes.

For example, sensory restoration might be used to provide an amputee with a sense of touch from a prosthetic hand. A device to achieve this might include a pressure transducer in the tip of a prosthetic finger to sense contact with objects. Information from that transducer would be encoded as stimulus pulses and passed through a stimulating electrode to activate the nerves in the user's arm. By varying the amplitude, frequency, or anatomical location of the stimulus pulses, the device could provide the user with a graded sense of touch that is perceived as emanating from the appropriate location on the hand.

Procedures for implementing sensory restoration are in the early stages of development, and, to date, devices to stimulate sensory pathways have been fairly crude and have only been tested in small populations. Experiments in animals have demonstrated that it is possible to inject sensory information into the nervous system, although it has been difficult to determine what those animals perceive during sensory stimulation. In one study, stimulating electrodes implanted in the median, ulnar, and radial nerves of a monkey evoked measurable responses in somatosensory cortex with appropriate latencies (Ledbetter et al. 2013). In another study, electrodes implanted in the dorsal root ganglia of cats were used to stimulate sensory

Peripheral Nerve Interface Applications, Sensory Restoration,

Fig. 1 A schematic of the implant used by Dhillon et al. (2004), to restore sensation in amputees. Fine wires were threaded through peripheral nerve stumps in the residual limb and electrical stimulation was used to evoke sensory percepts. (Reprinted with permission from Dhillon et al. 2004. © 2004 Elsevier)

afferents (Weber et al. 2011). Impulses were patterned after the firing patterns of sensory afferents recorded during leg movement, and the cortical response to stimulation was similar to the cortical response to leg movement.

Further studies have focused on sensory restoration in human subjects and have mainly focused on restoring cutaneous sensation and proprioception for amputees. Multiple studies have involved stimulation of the median nerve in healthy subjects and amputees, with subjects reporting experiences of throbbing, vibration, and fist clenching (Anani et al. 1977; Clippinger et al. 1974). In another set of studies, electrodes were implanted in the median nerves of amputees, with subjects reporting sensations of touch, joint movement, and limb position during stimulation. Some of those subjects (Fig. 1) demonstrated improved control of a prosthetic limb during sensory feedback (Dhillon et al. 2004; Dhillon and Horch 2005).

Effort has also been focused on stimulation of the sciatic nerve for sensory restoration in lower extremity amputees. In one study, stimulation was modulated based on prosthetic foot ground contact and knee angle (Clippinger et al. 1982). During stimulation, subjects demonstrated improved balance control and improved ability to function in the dark.

These results demonstrate the promise of sensory restoration, though significant future work will be required to establish stable electrical

interfaces with the peripheral nerve, develop a better understanding of the encoding of sensory information, and optimize the delivery of that sensory information into the nervous system.

Peripheral Nerve Interface Applications, Sleep Apnea

Dominique M. Durand
Department of Biomedical Engineering,
Physiology, Biophysics and Neurosciences,
Neural Engineering Center, Case Western
Reserve University, Cleveland, OH, USA

Definition

Obstructive sleep apnea (OSA) is characterized by frequent collapse of the upper airways (UAWs) during sleep, and patients with OSA experience many apneas (breathing pauses) during the night.

Detailed Description

The severity of this condition is graded by the apnea-hypopnea index (AHI) that indicates the number of apneic episodes per hour (normal AHI < 5 and severe AHI > 30). Sleep is therefore interrupted often, and this condition leads to a lowering of oxygen saturation in the blood. These patients often experience many symptoms such as chronic fatigue, impaired memory, congestive heart failure, decreased libido, and hypertension. This is a serious problem that affects 1–4% of the population (Gislason et al. 1988).

Both men and women are affected but in different numbers (Olsen et al. 1995). Several muscles contribute to maintain the patency of the airways with the genioglossus being the strongest contributor by generating tongue extrusion. Other muscles such as the styloglossus and the hypoglossus contribute to the activity of the tongue and generate retraction. During sleep however, muscle tone decreases, and as the genioglossus relaxes, the tongue collapses into the oropharynx and obstructs airflow (Schwartz et al. 1998).

Solution

The application of continuous positive airway pressure (CPAP) using a mask is the most common and a highly effective method to prevent airway collapse (Littner et al. 2002). However, only about half of patients with OSA can sleep comfortably with a mask. Surgical procedures such as uvulopalatopharyngoplasty (UPPP) can also help, but for many patients the symptoms can resume following surgery. Electrostimulation of the hypoglossal nerve is a more recent approach. Since the largest branch of the hypoglossal nerve carries efferent axons to the genioglossus muscle, stimulation of the whole nerve has been shown to generate tongue retraction and prevents obstruction of the airways. This can be achieved by placing a nerve cuff electrode around the hypoglossal nerve and applying electrical pulses to the nerve (Fig. 1). Animal studies have shown that stimulation of the hypoglossal nerve during sleep prevents obstruction (Sahin et al. 1999). Several clinical studies have also clearly shown that electrical stimulation delivered during the night to the hypoglossal nerve after the onset of sleep significantly reduced the mean apnea-hypopnea index during NREM and REM sleep stages and reduced the severity of oxyhemoglobin desaturation (Schwartz et al. 2001). The long-term stimulation was well tolerated with complete or nearly complete suppression of the apneas. Moreover, since the hypoglossal nerve carries almost exclusively motor fibers and only

Peripheral Nerve Interface Applications, Sleep Apnea, Fig. 1 Electrical stimulation for OSA: A cuff electrode is placed around the hypoglossal nerve to activate the genioglossus muscle and protrude the tongue. The stimulation can be either synchronized with respiration or open loop

few sensory fibers, the stimulation can be applied with sufficient strength and minimal discomfort, paresthesia, or pain or more importantly without waking the patient.

Implementation

There is no commercially available neural stimulation device at this time for this indication, but it is an active area of research and technological development. There are three companies currently involved in developing a neuro-prosthetic device for patients with OSA. All three approaches use a nerve cuff electrode placed on the hypoglossal nerve but differ in how and when the stimulation is applied. One design synchronizes the stimulation to inspiration since the airways may require

opening during this phase of breathing. Inspiration is detected with a pressure sensor (<http://www.inspiresleep.com/>). Another design also synchronizes the stimulation with the inspiration but uses plethysmography to detect inspiration (http://www.apnexmedical.com/downloads/Apnex_Medical_Fact_Sheet.pdf; http://www.apnexmedical.com/downloads/apnex_medical_hgns_therapy_faqs.pdf). Finally, a third design does not implement synchronized stimulation but applies pulse stimulation continuously to maintain the tone in the muscles to prevent collapse (<http://imtheramedical.com/>). All three start-ups are involved in clinical trials and should have a product in the market within a few years. Given the large number of patients with untreated severe OSA, the advent of this technology on the market should have a significant clinical impact.

Vagus nerve stimulation

Definition

Vagal nerve stimulation (VNS) is a device-based neuromodulation therapy for drug-resistant forms of epilepsy, depression, and other conditions, that stimulates nerve fibers in the cervical vagus nerve or auricular branch of the vagus nerve (ABVN) using intermittent pulses of current delivered through implanted or external, noninvasive electrodes. VNS works by modulating activity in the central nervous system (CNS) and other peripheral tissues supplied by the vagal nerves in the thorax and abdomen, evidenced by regional and diffuse changes in brain blood flow, metabolism, and electrical activity in the CNS, as well as changes in organ system function via direct stimulation of vagal efferents or by eliciting reflexes via stimulation of vagal afferents.

Detailed Description

Vagal Nerve Anatomy

The vagal nerves are the largest and most evolved nerves in the human body. Using acetylcholine (ACh) as a sole neurotransmitter, the vagal nerves mediate many sensory and parasympathetic functions within the autonomic nervous system. The left vagus comprises ~100,000 axons; 65–80% are visceral afferent sensory fibers with sensory receptors located in the aorta, heart, lungs,

esophagus, larynx, pharynx, gastrointestinal tract, and various visceral organs (Foley and DuBois 1937; Rutecki 1990). The vagi also supply sensory fibers to the outer ear canal via the ABVN. Vagal efferents project from the dorsal motor nucleus (DMN) of the vagus to their effectors. The afferent fibers project primarily to the nucleus tractus solitarius (NTS), where diffuse projections convey the visceral (and some somatic) sensory information throughout the central nervous system (CNS), including areas in the limbic system and cortex that regulate emotion. Many of the afferent fibers participate in autonomic reflexes involved in maintaining homeostasis; these have myelinated projections from the somata in the nodose ganglion to the NTS, DMN, area postrema, nucleus cuneatus, and medial reticular formation (Paintal 1973). The NTS directly communicates with the reticular formation, area postrema (AP), and DMN; it also indirectly communicates with the thalamus, hypothalamus, amygdala, cingulate gyrus, and orbitofrontal cortex via the locus coeruleus (LC) and parabrachial nucleus (PB) (George and Aston-Jones 2010; George et al. 2007).

Implantable and External VNS Systems and Emerging Applications

FDA-approved or CE-marked VNS can be administered through implanted or external, noninvasive electrodes connected to an implanted or external pulse generator. When implanted, a pacemaker-like device delivers intermittent pulses of electrical energy to the left or right cervical vagus nerve through helical or cuff electrodes in open-loop fashion. Noninvasive VNS devices come in two forms: (1) transcutaneous auricular VNS (taVNS or tVNS) devices stimulate the auricular branch of the left or right vagus nerve at the tragus and/or cymba/cavum conchae and (2) noninvasive cervical VNS (nVNS) devices stimulate the left or right cervical vagus nerve through the skin surface (Yuan and Silberstein 2016a, b, c). Implantable devices provide more selective neural interfaces at the expense of invasive surgery and postoperative complications, while noninvasive devices provide a lower-risk, nonsurgical option at the expense of treatment

specificity and challenges around patient compliance.

In the United States, implantable VNS devices (e.g., VNS Therapy System from LivaNova, Inc.) are approved for drug-resistant epilepsy and depression, but are only considered a medically necessary treatment for drug-resistant epilepsy (UnitedHealthcare 2018); noninvasive cervical VNS devices are approved for chronic or episodic migraine and cluster headache (e.g., gammaCore nVNS from electroCore, Inc.). A percutaneous tVNS system was recently approved in the United States for the treatment of opiate withdrawal syndrome (Bridge Stimulator from Innovative Health Solutions, Inc.). In the European Union (EU), implantable VNS devices are approved for epilepsy (LivaNova), depression, autonomic imbalance, and heart failure (e.g., CardioFit VNS System from BioControl Medical, Ltd); noninvasive cervical VNS devices (nVNS) are approved for chronic or episodic migraine and cluster headache, while transcutaneous ABVN stimulation devices are approved for epilepsy (NEMOS tVNS from Cerbomed GmbH), depression, and pain (VITOS tVNS from Cerbomed GmbH) (Ben-Menachem et al. 2015).

There are numerous emerging applications of VNS. These include, but are not limited to: autoimmune inflammatory disorders (e.g., rheumatoid arthritis and Crohn's disease), Alzheimer's disease, anxiety disorders, autism spectrum disorder, bipolar disorder, bulimia, cerebral palsy, chronic pain/back or neck pain, fibromyalgia, gastroparesis and other small bowel motility disorders, narcolepsy, obesity, obsessive compulsive disorder, sleep disorders, tinnitus, and Tourette's syndrome (Ben-Menachem et al. 2015; UnitedHealthcare 2018; Yuan and Silberstein 2016a, b, c). In most instances, VNS is delivered in an open-loop fashion, but responsive (e.g., AspireSR from LivaNova, Inc. (UnitedHealthcare 2018), which automatically triggers stimulation based on characteristic changes in heart rate that precede seizure onset in certain patients) and closed-loop systems are emerging based on research funded by the DARPA ElectRx program, NIH SPARC program and the GSK Bioelectronics Innovation Challenge.

Implant and Dosing Procedure

Under general anesthesia, the VNS device housing is surgically implanted and secured in the left chest wall. A stimulation lead is routed under the skin from the device housing to the left cervical vagus nerve. The helical electrode at the distal end of the stimulation lead is wrapped around the cervical vagus nerve and secured to surrounding tissue. After a 2+ week patient recovery period, the device is turned on and programmed with a wand-like device that is placed over the skin where the device housing is located. Stimulation is intermittent and commonly programmed for 30 s of monophasic, constant-current stimulation every 5 min. Individual parameters are adjusted on a patient-to-patient basis to fine-tune the therapeutic efficacy and minimize the occurrence and severity of side effects (Marangell et al. 2007).

Common side effects, such as dyspnea, cough, and hoarseness, depend on the intensity of the stimulus parameter settings, and furthermore on the nerve fibers activated by a stimulus. To minimize patient discomfort, the intensity is slowly increased over 2-week intervals until a balance between the maximum stimulus intensity and the patients' willingness to accept any side effects is located (George and Aston-Jones 2010). This process is often complicated and time consuming for the patient and physician. Table 1 summarizes the recommended protocol for stimulus parameter adjustments after implantation. Table 2 summarizes available device settings and common variations for epilepsy and depression (Labiner and Ahern 2007).

Therapeutic Mechanisms of VNS

Implantable VNS therapy has been available since 1994 in Europe and 1997 in the United States as a therapy for treatment-resistant partial-onset seizures, where it has helped tens of thousands of patients with drug-resistant temporal lobe epilepsy (TLE) experience significant seizure rate reductions. The use of VNS as an alternative therapy for drug-resistant major depressive disorder (MDD) came after epileptic patients reported mood improvements in the NeuroCybernetic Prosthesis System trials in the 1990s (Ben-Menachem et al. 1994) (and the successful

Peripheral Nerve Interface Applications, Vagal Nerve Stimulation, Table 1 VNS adjustment protocols (Labiner and Ahern 2007)

Efficacy enhancement protocol	Side effect reduction protocol
A. every 2 weeks, increase the pulse amplitude in 0.25–0.5 mA increments until the maximum tolerated level is reached (starting 2 ⁺ weeks after device implantation)	A. Reduce pulse amplitude
	B. Reduce pulse duration
B. Gradually increase the duty cycle if the maximum tolerated pulse amplitude fails to produce a therapeutic response after 1–3 months	C. Reduce pulse repetition frequency
	D. Reduce device on time

off-label use of antiepileptic drugs for mood disorders (Ballenger and Post 1980; George et al. 2000; Post et al. 1986)). Several treatment-resistant epileptic patients implanted with the VNS device reported mood enhancements that could not be explained by the VNS-mediated reduction in seizure frequency. Positron-emission tomography (PET) studies subsequently proved that VNS reduces cingulate activity, the same effect seen from many successful antidepressant therapies (George et al. 2000), and alters limbic blood flow and metabolism (Henry et al. 1998). Di Lazzaro et al. applied transcranial magnetic stimulation (TMS) over the motor cortex and proved that long-term VNS significantly decreases motor cortex excitability in epileptic patients that have received VNS therapy for 10 or more weeks (Di Lazzaro et al. 2004). In 2007, this experiment was repeated in VNS patients with MDD, where the same reductions in motor cortex excitability were seen (Bajbouj et al. 2007). Other investigations show VNS-induced changes in neurotransmitter levels (Ben-Menachem et al. 1995; Kralh et al. 1998). Due to these promising data, the first VNS device for the treatment of unipolar refractory MDD was implanted by Rush and colleagues

in 1998 (George et al. 2000; Rush et al. 2000). Response rates (i.e., a patient is a responder if a standardized depression rating scale score is reduced by 50% or more in response to the therapy) of 27–40% were observed after at least 8 weeks of VNS therapy; robust and durable antidepressant responses are seen after 12 or more months of VNS therapy (George et al. 2002, 2005). The FDA approved VNS for refractory MDD in July 2005.

Many of the VNS studies published to date conclude that VNS imparts its antiepileptic and antidepressive effects through the activation of vagal afferent fibers. This is a logical conclusion, because (1) the device is intended to treat neuronal network-level disorders in the CNS; (2) vagal afferent fibers primarily project to the NTS and onward to the LC, where a chemical lesion was shown to significantly attenuate VNS-mediated anticonvulsive activity (Kralh et al. 1998); and (3) evoked potentials from VNS have been repeatedly observed in neural recording/imaging studies. However, the conclusion that VNS works by activating unmyelinated C fibers of the vagus nerve (Woodbury and Woodbury 1990) is debated, because (1) destruction of C fibers does

not destroy the antiepileptic effect of VNS and (2) stimuli found to be effective in epilepsy are likely of insufficient strength to activate the unmyelinated, afferent C fibers (Evans et al. 2004; George et al. 2002). Various biophysical (Mourdoukoutas et al. 2018; Pelot and Grill 2018), phenomenological and machine learning approaches to VNS optimization (Ward et al. 2015) are in development, which could help to unravel the mechanisms-of-action of VNS therapy and lead to improved titration of VNS parameters for the various indications that are already in clinical use or approaching regulatory approval.

Peripheral Nerve Interface, Epineural Electrode

Lee E. Fisher

Department of Physical Medicine and Rehabilitation, University of Pittsburgh, Pittsburgh, PA, USA

Synonyms

[Nerve cuff electrode](#)

Definition

Epineural electrodes are neural interface devices that are placed on or around peripheral nerves. They include one or more electrical contacts that can be used to stimulate or record action potentials from those nerves. These devices are not designed to penetrate through the perineurium and therefore tend to provide macroscale, rather than microscale, interfaces with the nerve. Because the perineurium remains intact and the electrode contacts are relatively large, the interface tends to be stable over time and less sensitive to micromotion and encapsulation than a microelectrode interface. The size and epineural nature of these electrodes often result in a lower degree of selectivity, both for stimulation and recording, than can be achieved via a penetrating microelectrode interface.

Detailed Description

Epineural electrodes are devices designed to be placed on or wrapped around peripheral nerves to provide an interface for electrical stimulation and recording. There are a wide variety of device designs and configurations, but the structure (Fig. 1) typically includes a layer of insulating material, such as silicone, placed on or wrapped around the nerve along with one or more electrical contacts embedded in the insulating material. The insulating layer provides both mechanical stability and electrical insulation for improved recording as well as control of the flow of current during stimulation. For stimulation applications, this insulation and the intimate contact between nerve and electrode typically result in the activation of the nerve by significantly smaller currents than are required for muscle-based stimulating electrodes (Fisher et al. 2008). Depending on the application, the electrical contacts can range from a single, small square of conducting material to multiple large bands that wrap around the nerve. Electrical contacts are typically made of conducting metals such as platinum or stainless steel, although some newer designs use conducting polymers such as polypyrrole (Green et al. 2008). The contacts are connected to a set of leads which route signals away from the implantation site.

Stimulating Electrodes

A variety of epineural electrode designs have been implemented for stimulation applications with

Peripheral Nerve Interface, Epineural Electrode, Fig. 1 An epineural electrode. The device includes an insulating layer placed on or wrapped around the nerve and embedded with contacts connected to leads that route away from the implant site

varying degrees of clinical translation and varying degrees of success. Initial designs relied on plastic or rubber tubing wrapped around the nerve for the insulating layer (Dubkin 1970). These designs had significant potential for inducing nerve damage due to the high mechanical stiffness of the material and the occlusion of blood flow to the nerve. As such, a number of electrode designs were developed to mitigate these risks, while also working to improve the selectivity of epineural stimulation.

The Huntington Medical Research Institute helical electrode (Fig. 2) has seen the most clinical success, by far, of any epineural electrode to date (Amar et al. 2008). The simple device, which is designed to coil around the nerve, includes either one or two electrical contacts and is not intended to selectively activate individual fascicles within the nerve. Instead, the device has been used to stimulate the vagal nerve for applications that do not require selectivity such as the control of epilepsy and depression. The device has been implanted in over 70,000 patients to date (Cyberonics 2013).

The self-sizing spiral nerve cuff electrode (Fig. 3) was designed to wrap snugly around the nerve while still providing the ability to expand to accommodate swelling of the nerve tissue (Naples

et al. 1988). This design relies on differential stretching of two layers of silicone rubber to achieve a spiral shape that can expand and contract as the pressure within the cuff changes.

These devices have been implanted in human subjects at a variety of anatomical locations as part of neuroprostheses. In one study, a four-contact spiral nerve cuff was implanted around the right optic nerve of one subject with retinitis pigmentosa (Veraart et al. 1998). The subject reported experience of phosphenes in distinct locations around the field of vision during stimulation through each of the electrode contacts. In another study, nine spiral nerve cuff electrodes were implanted in the upper extremities of two individuals with paralysis from spinal cord injury (Polasek et al. 2009). Four-contact nerve cuffs were implanted around the radial nerves of two subjects and the musculocutaneous nerve of one subject. Six additional one-contact nerve cuff electrodes were implanted around the axillary, suprascapular, long thoracic, and thoracodorsal nerves of the same two subjects. Monopolar stimulation through each electrode could produce selective activation of at least one muscle. These

Peripheral Nerve Interface, Epineural Electrode, Fig. 2 The Huntington Medical Research Institute helical electrode, which has two contacts for nonselective bipolar stimulation and a third coiled section for added stability. (Adapted with permission from Amar et al. (2008). © 2008 IEEE)

Peripheral Nerve Interface, Epineural Electrode, Fig. 3 The self-sizing spiral nerve cuff electrode. As pictured, the device has four contacts designed to be equally spaced around the circumference of the nerve. Each contact can be connected to a separate channel of stimulation

electrodes were implanted for up to 3 years with little change in the response to stimulation. In a third study, eight spiral nerve cuff electrodes were implanted on bilateral femoral nerves of four individuals with paralysis from spinal cord injury (Fisher et al. 2008, 2009, 2013). These electrodes generated sufficient knee extension moment to facilitate standing in all subjects, and the response to stimulation was stable for up to 1 year after implantation.

While the self-sizing spiral nerve cuff has been shown to provide a highly stable stimulation interface with peripheral nerves, it has had limited success at selectively activating multiple independent muscle populations. In both animal experiments and human studies, the device has been demonstrated to selectively activate one or more muscles independently, but a single self-sizing spiral nerve cuff has not been demonstrated to selectively activate more than four muscles (Polasek et al. 2009; Fisher et al. 2009, 2013; Polasek et al. 2007). This limited selectivity results from both the number of contacts within

the electrode and the electrode's circular cross section, which causes fascicles near the center of the nerve to be equally distant from all contacts, preventing selective activation (Veltink et al. 1989; Altman and Plonsey 1988). This geometric limitation has led to the development of other designs that may be better suited for achieving selective activation of multiple fascicles.

The slowly penetrating interfascicular nerve electrode (SPINE) improves on the nerve cuff electrode design by including a larger number of contacts on fins (Fig. 4) that are designed to slowly penetrate into the epineurium but not through the perineurium, leaving fascicles intact (Tyler and Durand 1997). The device consists of silicon rubber tubing sliced longitudinally into four beams, with an element including three contacts extending radially into the lumen from each section of the tube. A second piece of tubing is wrapped around the body of the cuff to maintain closure of the electrode and generate the force required to allow the fins to penetrate into the epineurium. The SPINE was implanted acutely

around the sciatic nerves of six cats and achieved a moderate improvement in selectivity over the traditional nerve cuff design. The SPINE has not, however, undergone any chronic safety testing and, as such, has not been implanted in any human subjects to date.

The multigroove electrode (Fig. 5) is another device designed to penetrate the epineurium but leave fascicles intact (Koole et al. 1997). The device requires the surgeon to tease apart fascicles and place them into separate grooves during implantation. In one study, multigroove electrodes with two grooves were implanted on the sciatic nerves of eight rats and achieved selective activation of two branches of that nerve (Koole et al. 1997). As with the SPINE, to date, the device has not been translated for chronic human use.

Book electrodes (Fig. 6) are another class of epineural electrodes that avoid the geometric limitations of nerve cuff electrodes through the use of a more rectangular cross section. This cross-sectional shape decreases the distance between fascicles and contacts within the electrode and can improve the ability to selectively activate each fascicle. A variety of designs have been implemented including devices with a single lumen as well as others with multiple separate lumina. Separated lumina can be created with multiple flaps that divide the rectangular cross section (Brindley 1977). Book electrodes have seen wide clinical adoption as part of a neuroprosthesis to stimulate the sacral spinal roots for bladder control (Martens and Heesakkers 2011). The devices have been implanted in over 1500 patients and multiple studies have demonstrated their ability to selectively activate individual spinal roots and achieve stable interfaces lasting 16 years or more (Martens and Heesakkers 2011; Brindley 1994).

Another book-type electrode, the flat interface nerve electrode (FINE; Fig. 7), has a similar rectangular cross section but has multiple contacts along the lumen (Tyler and Durand 2002). The device differs from other book electrodes in that it is designed for use on the peripheral nerves, rather than the spinal roots, and is designed specifically to reshape round nerves to a flatter cross section. The device has multiple small electrical contacts designed to achieve a relatively high degree of selectivity and has been demonstrated to achieve sub-fascicle level selectivity on the sciatic nerve of cats (Leventhal and Durand 2003). To date, the device has been implanted acutely on the femoral nerves of six human subjects and has demonstrated the ability to selectively activate at least

four, but possibly as many as six, muscles (Schiefer et al. 2010).

Recording Electrodes

The electroneurogram (ENG) signal recorded from epineural electrodes consists of electrical

Peripheral Nerve Interface, Epineural Electrode, Fig. 7 The flat interface nerve electrode. The device is designed to reshape round nerves to a rectangular cross section to decrease the distance between fascicles and contacts in order to improve selectivity. As pictured, the device has eight contacts which can each be connected to a separate channel of stimulation. (Adapted with permission from Schiefer et al. (2010). © IOP Publishing. All rights reserved)

signals recorded from many axons simultaneously and is often contaminated by other bioelectric signals such as the electromyogram signal from nearby muscles. To reduce noise and improve signal-to-noise ratio (SNR), epineural recordings are usually performed in a tripole or virtual tripole configuration (Fig. 8). The tripole configuration relies on the double-differentiated potential recorded from a contact of interest and two nearby reference contacts aligned longitudinally with the nerve. The virtual tripole uses a similar configuration of contacts but shorts together the two reference electrodes and uses the difference between the signal of interest and the shorted references. These configurations have dual benefits of reducing common-mode noise and improving SNR by exploiting the triphasic nature of action potentials. By measuring the difference between potentials recorded longitudinally along the nerve, the tripole and virtual tripole configurations increase signal amplitude by measuring the peak-to-peak rather than absolute voltage from the triphasic action potential. By varying the spacing between contacts, these configurations can also provide some selectivity in recording action potentials from axons of specific diameters based on their associated velocities and wavelengths. The tripole configuration generally has better SNR but requires additional amplifiers near the electrode to perform the differencing operations, so the virtual tripole configuration is more commonly used in practice.

Peripheral Nerve Interface, Epineural Electrode, Fig. 8 Typical recording configurations for epineural electrodes. (a) Tripole configuration. The signal is double-differentiated with respect to two surrounding reference signals. (b) Virtual tripole configuration. The signal is differentiated with respect to the shorted surrounding reference signals

While the configuration of contacts is different for recording and stimulating electrodes, similar form factors have been used for both applications, with slight differences in design. Nerve cuff electrodes are commonly used for recording applications, though the insulating layer for recording versions is often longer than for stimulating versions. This is necessary to accommodate the additional contacts in the tripole and virtual tripole configurations.

A number of studies have used nerve cuff recordings from the common peroneal and sural nerves to detect foot contact for closed-loop neuroprostheses to correct foot drop (Hansen et al. 2003; Hoffer et al. 1996). Another study placed a nerve cuff electrode around the radial nerve to detect slip at the fingertips as part of a neuroprosthesis to restore hand grasp after spinal cord injury (Hoffer et al. 1996). Many animal studies have relied on cuff electrodes and FINEs for recording ENG signals from nerves throughout the body (Hoffer et al. 1987, 1996; Yoo and Durand 2005; Wodlinger and Durand 2011). Some of those studies have also focused on the development of techniques such as beam-forming and blind source separation to selectively record from individual fascicles within mixed nerves (Wodlinger and Durand 2009, 2011; Calveti et al. 2011).

Peripheral Nerve Interface, Intraneural Electrode

Mitch Frankel
Salt Lake City, UT, USA

Definition

Peripheral nerve intraneural electrodes are characterized as having the active recording or stimulation contact located within the epineurium sheath of a peripheral nerve. The most common intraneural electrodes have active contacts within the smaller nerve-fiber bundles of the fascicle.

Detailed Description

Peripheral nerve intraneural electrodes were originally developed to improve the selectivity and signal-to-noise ratio of neural recordings using microneurography techniques. This allowed researchers to acquire single-unit afferent action

potentials by using needle electrodes placed within the endoneurium of individual nerve fibers. The most common intraneural electrodes have active contacts that are placed inside the perineurium of the smaller fascicle nerve bundles; thus, these electrodes are referred to as intrafascicular electrodes. The electrode technology has since been improved and expanded to multi-site recording and stimulating electrodes. Stimulation via intraneural electrodes requires less current to generate muscular force producing action potentials than stimulation through extraneural electrodes. Intrafascicular electrodes also provide a way to selectively activate small groups of motor units within a single muscle, which can provide fine-tuned gradation of force production from a single muscle. Intraneural electrode technology development can be grouped into three distinct groups based on the design of the electrodes: longitudinal intrafascicular electrodes (LIFEs), microelectrode arrays (MEAs), and sieve electrodes (Navarro et al. 2005).

Longitudinal intrafascicular electrodes, or LIFEs, are a Teflon-insulated Platinum-Iridium wire, 20–30 cm in length and 25 μm in diameter with 1 mm of exposed wire. The LIFE is surgically threaded beneath the perineurium of a fascicle with the length of the insulated electrode running longitudinal to the nerve fibers. Early versions of the LIFE were shown to be effective for stimulation selectivity and multi-unit recording. Recent research has used chronically implanted LIFEs to evoke object discrimination through afferent sensory stimulation in upper-limb amputees using strain-gauged myoelectric prostheses. Modifications have been made to the standard LIFE to add multiple electrode contact sites and improve on implantation techniques and mechanical stiffness. Polymer-based LIFEs (polyLIFEs) have been created that use a more flexible metallized Kevlar fiber. These polyLIFEs have been used in human upper-limb amputee research to record peripheral motor neuron activity for control of grip force and hand position of a mechanical prosthesis, as well as to return tactile and proprioceptive sensory information via stimulation. A version of the LIFE using a shape

memory alloy wire allows the electrode contact site to be micromanipulated after implantation. Thin-film LIFEs (tLIFEs) were created to improve on the mechanical mismatch between metal wires and neural tissue. Multi-contact tLIFEs have been implanted chronically in human upper-limb amputees and have been used to decode motor intent for various hand positions as well as return tactile information from a phantom hand. The transverse intrafascicular multielectrode (TIME) uses an electrode similar to multi-contact tLIFEs but threads the electrode transversely across the nerve. Threading the electrode across one or more fascicles allows for greater selectivity because more individual nerve fibers are likely to be in proximity to the multiple electrode contacts. Modifications to LIFEs and the TIME, including multiple filaments and corrugated structures, allow for increased electrode count and separation between contact sites to improve recording and stimulation selectivity as well as provide better chronic implantation stability (Ortiz-Catalan et al. 2012; Yoshida et al. 2010).

Microelectrode arrays (MEAs) were originally developed for cortical recording experiments and are designed to penetrate neural tissue. MEAs commonly consist of either a thin penetrating substrate with multiple electrode contact sites or a grid of penetrating microelectrodes. Only a few MEAs have been translated to peripheral nerve applications. The most commonly used peripheral nerve MEA is the Utah Slanted Electrode Array (USEA) which is a 10×10 grid of penetrating microelectrodes that vary in length from 0.5 to 1.5 mm and have 400 μm spacing. The USEA is pneumatically inserted into the peripheral nerve, and the grid spacing and varied depths of electrodes on the USEA allow for good cross-sectional electrode tip coverage across the diameter of a peripheral nerve. This provides a high level of selectivity for single and multi-unit recordings from various afferent and efferent nerve fibers throughout the nerve, as well as very selective and graded muscle force production from multiple muscles using stimulation currents below 100 μA . There have been some human

studies using MEAs in peripheral nerves, but the majority of the research has been done with animal studies. Some of the various applications include using the USEA as a neural recording platform to decode limb positions and using the USEA as a neural stimulation platform to control bladder function. A large body of animal research using acute and chronically implanted USEAs has focused on interleaved multielectrode stimulation to evoke fatigue-resistant coordinated movements using multiple muscles across multiple skeletal joints (Navarro et al. 2005; Ortiz-Catalan et al. 2012).

Sieve electrodes are an intraneural peripheral nerve interface that is mainly used for the regeneration of severed nerves. The sieve is made up of a polymer disk with metallized holes for use as electrodes and is placed in the middle of a chamber in close proximity to the two ends of a severed nerve. When the nerve fibers from the severed ends regrow and connect through the metallized holes, they interface with the electrode contacts. Stimulation via these electrodes may also improve axonal regrowth. Sieve electrodes were originally designed with holes that had similar diameter to single nerve axons (2–10 μm) to provide a high level of selectivity, but it was found that nerve regeneration failed with such small holes. Nerve fiber regrowth requires long-term chronic studies, and sieve electrodes have only been tested in animal research (Navarro et al. 2005; Ortiz-Catalan et al. 2012).

Definition

Regenerative peripheral interfaces (RPIs) are implantable devices that rely on the spontaneous regenerative capability of the injured peripheral nervous system to establish a bidirectional flow of information between the transected nerves in amputees and smart robotic prosthetics. RPIs are designed to provide intuitive movement and natural feel to advanced prosthetics for amputees and are characterized by the placement of multi-electrode arrays (MEAs) in the regenerative path of their transected peripheral nerves. The MEAs detect motor commands from the brain as extracellular action potentials (AP) in the microvolt range traveling down their amputated nerves and use them to control the robotic prosthetic limb. In addition, RPIs can translate information from sensors populating the robotic limb to the user, by electrically stimulating axons in the nerve that elongate from neurons in the dorsal root ganglia.

Detailed Description

Regenerative Peripheral Interfaces (RPIs)

RPIs constitute a selective yet invasive type of peripheral nerve interface device first proposed in the early 1970s, as transected nerves were shown to grow through porous materials or into grooves (Brindley 1972; Mannard et al. 1974), leading to the idea microelectrode arrays with holes can be fabricated for recording from axon

fibers the regenerating through (Llinas et al. 1973). The first regenerative electrode was fabricated by drilling holes through silver wires to record multiunit potentials from regenerated *Xenopus* motor fibers (Mannard et al. 1974). Subsequently, chronic recordings of action potentials were obtained in the regenerated rabbit sciatic nerve using a 10-channel silicon-based sieve electrode (Edell et al. 1982). Advanced micro-fabrication techniques allowed the development of sieve multielectrodes capable of both recording and stimulating from regenerated fibers.

Types of RPIs

Several RPI devices have been developed, including those that rely on the regeneration of transected axon through perforated devices, microchannel electrode arrays, and electrodes placed in the lumen of nerve guides. The main types include the following:

Sieve Electrode Array

In this type of RPI, the regenerating axons are interfaced as they grow through a perforated substrate resembling a sieve, with ring electrodes on some of the holes. The first report of neural recording using this type of electrode was published by Edell (1986), who used a sieve electrode etched in silicon and wired to a percutaneous connector, to record spontaneous and evoked neural activity from the regenerating rabbit peroneal nerve. This work was extended by Bradley et al. (1997), who recorded neural activity using a sieve electrode implanted into the rat glossopharyngeal nerve for up to 13 weeks, in response to taste and thermal stimuli in the tongue. Regeneration was also demonstrated in sieve electrodes implanted in rat lumbar spinal roots and in the eighth cranial nerve of the toadfish.

However, the silicone sieve design proved to partially block nerve regeneration allowing only a small fraction of primarily sensory neurons to grow through the perforations. In addition, these electrodes also cause compressive axon damage due to the inability of the ring electrodes to accommodate the increment in fiber diameter

that axons undergo as they mature and remyelinate (Navarro et al. 1998). The development of softer polyimide sieve electrodes alleviated some of these limitations and improved reliability (Stieglitz 1997; Lago 2007). However, recordings have been obtained only in a subset of the animals tested, and a low proportion of the electrodes on the sieve provide recordable signals (Lago et al. 2005).

A modification of the sieve electrode in which regenerating axons terminate in a compartment that contains cells that serve as surrogate targets for the regrowing axons, known as biohybrid arrays, has been proposed, but has not been implemented or tested (Stieglitz et al. 2002).

Microchannel Electrode Array (MCE)

In this device, regenerating axons grow through a nerve conduit with microchannel electrodes after directly suturing the severed nerve. This design was first proposed by Susuki and colleagues (1997) who fabricated them in polyimide with multiple channels for recording and stimulating sites which allow the regeneration of axons. More recently, MCE are fabricated using soft polymers such as polyimide or polydimethylsiloxane (PDMS; Lacour 2008). The size of the microchannels has been demonstrated to be critical as 70% regeneration ensues through 100- μ m-wide channels but fails if channels are 35 μ m (Lacour 2009). The length is also critical as regeneration can be achieved through 4–5-mm-long microchannel arrays, but with a much reduced quality in implants longer than 1 cm. In addition, the regenerated “mini nerves” are ensheathed with fibrous tissue that sometimes can cover up to half of the available channel area. Such mini nerves were recently proven by Fitzgerald et al. (2012) to be functional by inserting a fine tungsten microelectrodes into the silicone array.

Recently, Minev et al. (2012) demonstrated the recording of tactile-evoked nerve activity in anesthetized rats using gold electrodes patterned into PDMS microchannels, in which small fibers teased from the dorsal roots were threaded inside the microchannels in acute experiments.

While MCE are a promising new type of RPI, recording and stimulating of regenerating fibers in fully awake animals remain to be demonstrated.

Regenerative Multielectrode Interface (REMI)

This interface relies on a microelectrode array placed in the lumen of nonbiodegradable polyurethane tube that serves as a nerve guide. The transected peripheral nerve is sutured to both ends of the REMI conduit allowing axons to regenerate through the platinum MEA in the lumen with minimal or no restriction. This type of regenerative interface is completely encapsulated by the regenerated tissue during nerve repair, forming a monolithic structure that anchors the RPI to the nerve, making it less susceptible to micromotion injury. The REMI was demonstrated to record action potentials as early as 8 days post implantation, with high signal-to-noise ratio, and for as long as 3 months in some animals, with minimal inflammation at the nerve tissue-metal electrode interface (Garde et al. 2009). This electrode allows normal nerve regeneration across the nerve conduit, and the recording of spontaneous and evoked action potentials in fully awake animals, as indicated by a battery of behavioral tests including plantar mechanoreception and thermal nociception assays.

Seifert and collaborators (2012) used a high-throughput gene array to confirm that the REMI does not interfere with normal regeneration as indicated by the normal expression of genes involved in nerve inflammation, cell death, neural injury and repair, and the histological changes that occur in parallel to early neural activity.

Regenerative interfaces are unique in that biological cues can be used to guide the regenerative path of growing axons into compartmentalized electrodes, a strategy suggested to achieve modality-selective regenerative neural interfaces. This possibility has been supported by reports indicating that NGF and NT-3 can selectively attract TrkA nociceptive axons and TrkC proprioceptive axons *in vitro* and partially *in vivo*; respectively (Lotfi et al. 2011). However, the

feasibility of modality-specific neural interfacing in segregated REMIs remains to be demonstrated.

Limitations

Invasiveness

The implantation of RPIs requires invasive surgery; however, this might be justified in most amputee cases in which the transected nerve in the limb stump remains functional but disconnected from its normal targets.

Nerve Regeneration Interference

Electrodes placed in the regenerative path of axons can actually present a physical barrier to their growth. Indeed, target innervation success is reduced compared to that of nerves regenerating through a nerve guide without regenerative electrodes. This limitation has been characterized as drastic in the sieve interfaces, where only 10% of regenerating myelinated axons succeeded in crossing the electrode, most of which are sensory and not motor axons.

Definition

Peripheral nerve models are computational models of one or more axons. Many models have been created. Variation in models typically pertains to the specific ionic currents and their conductances through the axon membrane. Another common variation pertains to the method used to model myelination. Typically, peripheral nerve models are nonlinear in nature and require solving systems of differential equations, although there are fast approximation techniques that can provide insight into the trends in axonal response to varied stimulation. In the neurosciences, peripheral nerve models are more typically used to study single neurons, whereas, in biomedical and neural engineering, peripheral nerve

models are more typically used in large population models to study the global response to electrical nerve stimulation or for nerve recording, primarily for use in functional electrical stimulation (FES) neuroprosthetic or neuromodulation systems.

Detailed Description

Anatomy

Briefly, peripheral axons fall within two categories – myelinated and unmyelinated – depending on the presence of periodically spaced sheaths of myelin enrobing the axon. A small portion of the axon membrane remains exposed between adjacent myelin sheaths known as the node of Ranvier. Both types of axons frequently appear in fascicles – bundles of axons within a nerve that are isolated from each other by a perineurial sheath. The axons within a fascicle are collectively referred to as endoneurium. The remainder of the nerve is referred to as the epineurium. Peripheral nerves can contain anywhere from a single fascicle to dozens of fascicles and the same nerve across species can contain a vastly different number of fascicles.

Note, within this entry, the term “nerve” will be used to refer to a population of axons and is not to be confused with the axon, or neuron, itself. Additionally, the models discussed in this entry are electrochemical in nature. Mechanical models of nerves will not be addressed.

Applications

The basis of all peripheral nerve models is the axon. Individual models of axons may be used to accurately represent experimental data. These models tend to be more detailed, incorporating numerous types of ion channels. They may also incorporate sophisticated representations of myelination and the space between the myelin and the axonal membrane: the periaxonal space. Used alone, this type of model can be used to provide insight into how an axon will respond to direct extracellular or

intracellular stimulation. This type of axon model may also be used *en masse* to study or predict the response of nerves to electrical stimulation, a common technique in the field of neural engineering. Additionally this technique can be used to model nerve recording. To this end, population models may incorporate a volume conductor model in which the spread of voltage (potential) in space is determined.

Alternatively, axon models may be simpler and designed not with the intent? of perfectly reproducing the shape of the action potential or studying the effects of electrical stimulation on a nerve. Instead, these models are mostly interested in the binary nature of neurons (the so-called “all-or-none” response) and are typically used to assess the flow of information in neural networks. As neural networks are more accurate models for the central nervous system, they are beyond the scope of this entry.

The Cable Equation

Before discussing specific models, it is important to discuss the cable theory, as it is the basis for all peripheral axon models. The cable theory was developed to describe signal propagation and decay in underwater cables, specifically those used for transatlantic telegraphs. Scientists in the late nineteenth century recognized similarities between peripheral axons and cables and began to apply them to axon models. The cable, or axon, can be represented by a circuit (Fig. 1).

Where C_m and R_m describe the membrane capacitance and resistance, respectively, and R_i describes the internal resistance to current flow. Although this model is strictly electrical in nature, it is analogous to ionic flow in the nerve. The analysis of this model produces the equation

$$\lambda^2 \frac{\partial^2 V_{\tau d}}{\partial x^2} - \tau \frac{\partial V_{\tau d}}{\partial t} - V_m = 0$$

$$\tau = C_m R_m$$

and

$$\lambda^2 = \frac{R_{\tau d}}{R_i}$$

This equation describes the deviation in membrane voltage from a resting potential, $V_m = V_i - V_e$, as a function of distance along the axon, x , and time, t . This model was subsequently adapted to account for insulative myelin and the resting membrane voltage, V_r , typically assumed to be -65 mV (Fig. 2).

This model was further refined to account for specific ionic currents that cross the membrane. These adaptations will be discussed in the following sections.

The Hodgkin-Huxley Model

In 1952, Sir Alan Hodgkin and Sir Andrew Huxley published a seminal series of papers that

Peripheral Nerve Models, Fig. 1 An electrical circuit representation of a passive, unmyelinated axon. Compartments of membrane resistance, R_m , and capacitance, C_m , are separated internally by resistance within the axon, R_i

Peripheral Nerve Models, Fig. 2 Adaptation of the circuit shown in Fig. 1 to account for myelination. Here, the extracellular voltage, V_e , can differ at each node, n .

A battery is included to maintain resting membrane voltage or reversal potential, V_r , typically -65 mV

detailed the dynamics of ion channels in a node of Ranvier in the squid (*Loligo pealei*) giant axon. Their model captured the dynamics of a propagating action potential as a function of voltage-gated sodium and potassium ion channels as well as a leakage current that accounted for the transmission of all other ions. The researchers recognized that whether the ion-selective channels in the axonal membrane allowed the flow of an ion depended on both membrane voltage and time. That is, the membrane resistances in the cable model were ion specific and variable. The equivalent electrical circuit for the membrane was adapted to Fig. 3.

Using circuit analysis,

$$I = I_C + I_{Na} + I_K + I_L$$

can be expanded to

$$I = c_m \frac{dV_m}{dt} + g_k(V_m - E_K) + g_{Na}(V_m - E_{Na}) + g_L(V_m - E_L)$$

where $g_x = 1/R_x$, the conductance of ion x . Hodgkin and Huxley explicitly defined the ionic conductances as functions of time and voltage, thus allowing them to further expand the equation to

$$I = c_m \frac{dV_m}{dt} + \bar{g}_K n^4 (V_m - V_K) + \bar{g}_{Na} m^3 h (V_m - V_{Na}) + \bar{g}_L (V_m - V_L)$$

where $\bar{g}_{Na}$, $\bar{g}_K$, $\bar{g}_L$ and refer to the maximum sodium, potassium, and leakage conductance, respectively. E_{Na} and E_K are the equilibrium potentials for sodium and potassium. Additionally, Hodgkin and Huxley determined the probability that a voltage-gated sodium channel, m^3h , or potassium channel, n^4 , was open. These probabilities are themselves dependent on voltage and time:

$$\begin{aligned} \frac{dn}{dt} &= \alpha_n(1-n) - \beta_n n, \quad \alpha_n = \frac{V_m + 10}{100 \left(e^{\frac{V_m + 10}{10}} - 1 \right)}, \quad \beta_n = 0.125 e^{\frac{V_m}{20}} \\ \frac{dm}{dt} &= \alpha_m(1-m) - \beta_m m, \quad \alpha_m = \frac{V_m + 25}{10 \left(e^{\frac{V_m + 25}{10}} - 1 \right)}, \quad \beta_m = 4 e^{\frac{V_m}{18}} \\ \frac{dh}{dt} &= \alpha_h(1-h) - \beta_h h, \quad \alpha_h = 0.07 e^{\frac{V_m}{20}}, \quad \beta_h = \frac{1}{10 \left(e^{\frac{V_m + 30}{10}} + 1 \right)}, \end{aligned}$$

Following the seminal work of Hodgkin and Huxley, many researchers adapted the H-H model, incorporating additional ion channels and adjusting maximum conductances and reversal potentials in an effort to accurately describe the particular axon under investigation.

Peripheral Nerve Models, Fig. 3

Adaptation of the simplified nodes shown in Fig. 2 to account for different ionic currents and reversal potentials. Transmembrane sodium current, I_{Na} , is assumed to be governed by a single type of sodium channel, as is potassium current, I_K

Accounting for Myelin

While the work of Hodgkin and Huxley, Frankenhaeuser and Huxley, and many others was instrumental to the fields of computational neuroscience and neural engineering, many treated the myelin between the adjacent nodes of Ranvier as a perfect insulator, resisting all ionic current flow through the axonal membrane. Depending on the application, this simplification may be acceptable, but research has shown that this is not true. Other models have attempted to account for myelin.

In 1962, Richard FitzHugh represented myelin as a series of passive high-impedance compartments consisting of a capacitor and resistor in parallel similar to that shown in Fig. 1. Model results better represented observations from mammalian axons. However, models were unable to reproduce common features of mammalian action potential spike trains such as depolarizing afterpotentials. Such detail was not captured until the introduction of the double-cable axon model, which accounted for the periaxonal space between the myelin and the axon (Fig. 4).

In 1985, Blight characterized myelin as a 10-compartment circuit model, accounting for the internodal (i) and myelin sheath (my) capacitance and resistance. In 1990, Awiszus expanded this representation to include potassium and sodium currents in parallel through the intranodal axonal membrane. A year later Halter and Clark

refined the model to account for differences in myelin thickness along the internode: the myelin adjacent to the node (MYSA), the fluting of the myelin (FLUT), and the stereotypical myelin with uniform thickness (STIN). This model has been subsequently refined to include different types of ion channels, such as slow potassium, fast potassium, fast sodium, and persistent sodium channels, and electrogenic ion pumps (Stephanova and Bostock 1995). In 2002, McIntyre, Richardson, and Grill published a double-cable axon model, commonly referred to as the MRG model, which is considered to be a very accurate representation of a mammalian peripheral axon to electrical stimulation.

Extensions of the Single Axon-Model: Volume Conductors and Populations of Axons

When the response of an axon to extracellular electrical stimulation is of interest, the distribution of potential (voltage) within a volume conductor must be determined. The simplest representation of volume conductor is that of a homogenous, isotropic medium in which the source of stimulation is at a sufficiently far distance from the axon so as to represent the source as a point source. In such cases, the voltage at each node of Ranvier and along each internode can be calculated by the equation

Peripheral Nerve Models, Fig. 4 To account for the space between the axon membrane and the myelination, the periaxonal space, the double-cable axon model was developed, which utilizes two modified cable models in

parallel. This model has subsequently been modified to account for different ionic currents, similar to those seen in Fig. 3

$$V = \frac{I}{4\pi\sigma R}$$

where σ is the conductivity of the medium and R is the distance from the point source to the location of interest along the axon. There are alternative equations to describe the voltage associated with a disc electrode as well as when the medium does not satisfy the assumptions of homogeneity and isotropy, such as when an electrode is on the surface of the skin. Typically, as models become more complicated and incorporate more tissues with dissimilar conductances, researchers turn to finite element models, commonly referred to as finite element method (FEM) or analysis (FEA).

The techniques described above can be extended to simulate populations of axons, such as would be encountered when electrically stimulating or recording from a peripheral nerve. In these cases, each axon is typically treated independently with the underlying assumption that no axon directly impacts the reaction of any other axon to electrical stimulation. With the continued improvement in computing power and access to

computer clusters, a few researchers have developed full-nerve, three-dimensional, multi-fasciculated population models. While most of these studies have simplified fascicular geometry, assuming fascicles to be of equal size and uniform distribution, a few studies have based the nerve model on histological cross sections taken from the nerve being modeled, the largest study of which was published recently by Schiefer et al. (2012).

Time Considerations

As the complexity of the models increases, the time required to simulate the axon(s) does as well. With the computing power of today's computers, this time cost can be tolerated for a small number of axons. However, simulating large populations of axons or conducting sensitivity analyses with a fine resolution of the swept variable can lead to extended simulation times, even if parallel computing techniques are employed. The appropriate model depends on the nature of the study.

Typically, the simplest model that can sufficiently answer the question is optimal.

Simplifications and Approximations

Due to the computational overhead required to simulate large populations of axons, researchers have attempted to develop other techniques that approximate axon activation without the need to simulate the non-linear dynamics of the axon. Many of these techniques only captured axonal behavior under a narrow set of conditions. In 1992, Warman published a predictive method that accounted for the redistribution of internal currents and captured more axonal behavior, but still broke down under certain conditions. Recently, Peterson published a method that overcame some of those limitations while remaining fast.

Software Packages

Multiple software packages exist to simulate ion channels, single axons, networks of axons, populations of axons, and volume conductors. NEURON is a freeware designed specifically to model axon dynamics and is easily adaptable to facilitate addition or manipulation of ion channels. The Scientific Computing and Imaging (SCI) Institute at the University of Utah has also released software to simulate neuron responses to electrical stimulation. Of course, these models can also be developed in programming languages such as C/C++ or MATLAB. Neurocal is a MATLAB-based modeling package freely available on the MathWorks File Exchange. While there are numerous finite element packages, many cannot handle the complexity of most neural models. Exceptions include SCIRun, COMSOL, and ANSYS (formerly Ansoft) Maxwell.

Peripheral Nerve Signal Processing, Denoising

Ken Yoshida

Department of Biomedical Engineering, School of Engineering and Technology, Indiana University-Purdue University Indianapolis (IUPUI), Indianapolis, IN, USA

Synonyms

Filtering; Noise attenuation; Noise cancellation

Definition

A signal-processing method used to decrease or eliminate noise from a peripheral nerve recording through the attenuation or estimation and subtraction of the components of the raw electro-neurogram of non-nerve action potential origin or not of interest.

Detailed Description

The raw electrical activity obtained through electrodes placed in or around the peripheral nerve consists of the extracellularly measured propagating action potentials of the active fibers within the nerve bundle along with the superimposed electrical pickup from other nearby bioelectrically active tissues and non-bioelectric sources. Since the signal of interest, the nerve activity, can be orders of magnitude smaller than the noise in the raw electro-neurograms, signal processing to denoise the recording is necessary. Noise attenuation or denoising is an optimization that maximizes the signal and minimizes the noise to improve the signal-to-noise ratio of a recording to facilitate the extraction of signal or information in subsequent signal-processing steps. Thus, by definition, it is important to know something about and understand the nature of the detectable nerve signal and noise sources seen by the receiver.

Peripheral nerve bundles contain a multiplicity of nerve fibers that project to/from the central nervous system to peripheral end organs. Each peripheral end organ is typically wired to a single nerve fiber (axon). The nerve fiber and the end organ(s) it innervates are the smallest unit of control available to the body and is called the sensory (afferent) or motor (efferent) unit. The nervous system conveys information from one part of the body to another using a bioelectric impulse, the action potential, that travels up (afferent) or down (efferent) the nerve fiber. This communication is digital in that the unitary action potential by itself only conveys that an event has happened. It can be considered a single digital bit of information. Magnitude is conveyed in two ways: by modulating the frequency of action potentials transmitted through a single nerve fiber (rate code) and by modulating the number of fibers projecting to/from the end organ (population code).

Neural interfaces detect the information contained within the nerve bundle by measuring the extracellular action potential as they transit the region of sensitivity of the neural interface through a low-noise, high-input impedance electrometer (headstage amplifier). In general, the activity that is captured is the superimposed activity of many nerve fibers. The mass activity modulates as a function of both the rate and population codes and thus the energy of the nerve activity. Neural interfaces designed to resolve the activity of single nerve fibers (single-fiber action potentials or SFAP), additionally, can resolve the rate code of a small subset of that total population.

The extracellular action potentials detected are at most on the order of ~ 100 μV in amplitude and occupy a bandwidth between ~ 100 Hz up to several 10 's of kHz. The distance of the active nerve fiber to the electrode contact, electrode contact size, and impedance of the space surrounding the nerve and electrode have a large effect on the magnitude and bandwidth of the action potential detected. Neural interfaces with small contacts ~ 10 μm immediately in contact with the nerve fiber (< 50 μm distance and intrafascicular) can record extracellular action potentials on the high end of the amplitude and bandwidth range, while those with larger contacts and greater nerve fiber

Peripheral Nerve Signal Processing, Denoising, Fig. 1 (continued)

to electrode distances ($>100\ \mu\text{m}$ distance and extrafascicular) will have amplitudes in $\sim 1\ \text{uV}$ range and $<10\ \text{kHz}$ bandwidth (Yoshida and Stein 1999; Stein et al. 1975).

Noise sources of bioelectric in origin include the bioelectric activity of the heart and nearby muscles. They may also include the extracellular action potentials of nerve fibers that do not project to the activity of interest. Non-bioelectric noise sources include chemoelectric (electrode potential changes in temperature, environmental chemical species concentrations), mechanical disturbances to the electrode Stern layer (motion artifact), electromagnetic pickup of radio-frequency sources, and electrical power lines (Webster and Clark 2010) (Fig. 1).

Noise attenuation processing techniques exploit the differences that exist between the extraneural action potential and the various noise sources. Current methods (1) estimate the noise and subtract the noise estimate (differential recording) and (2) take advantage of differences in the frequency content of nerve activity and noise (spectral filtering) (Ge and Farina 2013).

Differential Recording

Potentials are by definition measurements relative to a point defined as ground. For biopotential measurements, a single ground point is defined on the body by the ground electrode. This point serves as the reference potential for all potentials as well as the common current return node for the headstage amplifier. The record of the raw electrical potential measurements relative to the ground electrode is defined as the monopolar recording.

In general, the ground electrode is a large, low-impedance electrode that is not matched in size or impedance to the active electrode. As such, the noise pickup is dominated by the active electrode (Purves 1981).

The simplest method to reduce noise in a recording is to place a second, size-matched electrode in the vicinity of the first active electrode such that it picks up common environmental noise but is insensitive to the nerve activity. This electrode is called an indifferent electrode and provides an estimate of the environmental noise seen by the active electrode. This estimate can then be subtracted either in hardware through a differential amplifier or later in software by a simple subtraction to eliminate some or all of the environmental noise in the measurement. Recordings that result from the subtraction of the noise with respect to an indifferent electrode are defined as the unipolar recording. A more advanced technique is to apply an adaptive filter that predicts the nonneural noise components in the monopolar recording, which can be subtracted to optimally remove the environmental noise.

Alternatively, a second active electrode displacing longitudinally or laterally the nerve but in the vicinity of the first active electrode could be used instead of the indifferent electrode. This case is defined the bipolar recording configuration. The configuration eliminates the need for an indifferent electrode and is effective for environmental noise attenuation but results in a complicated recording case where the activity measured is the sum of the activity of the uncommon nerve activity and the difference of the common nerve activity.

Peripheral Nerve Signal Processing, Denoising, Fig. 1 Analysis of recordings taken from the peripheral nerve in the frequency domain (spectrograms) and the time domain at various stages of denoising. The time domain records are shown at three zoom levels. The lowest zoom level resolves the rate or mass activity, while the highest zoom level resolves the single-unit action potential. The upper row shows the raw monopolar recording, while the second row shows the same recording after (1) subtraction of the indifferent recording and (2) band-pass filtering. The frequency

domain figures show the spectrograms for high levels of nerve activity and no nerve activity (or noise). Note the inclusion of in- and out-of-band noise in the monopolar recording case, which are largely eliminated through the subtraction from the estimate of the noise. Finally, band-pass filtering was applied to reveal the single-unit activities. Once the single-unit activity is resolved, the rate code can be captured. Alternatively, the focus can be an estimate of the population code, through analysis of the mass activity

Differential recording does not eliminate noise that presents themselves independently on each active or indifferent electrode channel, such as non-common mode bioelectric activity, stochastic thermal noise, or shot noise.

Spectral Filtering

Spectral filtering advantage of differences in the frequency composition of the extracellular action potential and noise sources. It defines the bandwidth of nerve activity as the signal and spectral frequencies that lie outside the bandwidth of interest as noise. The bandwidth of nerve activity ranges between ~100 Hz and 6 kHz (Stein et al. 1975) or 30 kHz (Qiao et al. 2012) depending upon the type of neural interface used. Typically, two classes of filters, band pass and notch, are used to filter raw electroneurograms. Band-pass filters are used to attenuate out-of-band noise such as the electrode interface potential, ECG, distant EMG, and out-of-band thermal noise. Notch filters can be applied to reduce the line noise and its harmonics which can extend into the bandwidth of nerve activity. It should be noted that noise sources that share the neural bandwidth, in-band noise, are not attenuated by these spectral methods.

Spectral filters can be implemented as classical linear filters in hardware or software or by applying classical linear filters (FIR, IIR, FIR-IIR). Although these filters can effectively reduce the out-of-band noise, they can also distort the waveform and introduce artifacts and instability depending upon the definition of the filter order (cutoff sharpness), filter type (Chebyshev, Paynter, Butterworth, Bessel), and passband selection. Generally speaking, these artifacts occur with higher-order and narrowly defined filters with filter types designed to have a steeper roll-off. If waveform fidelity is important, then lower-order filters or filters with flatter roll-off in the frequency domain (Bessel) or digital multiresolution, wavelet, or decomposition techniques (Strang and Nguyen 1997; Mallat 1999; Citi and Micera 2013; Citi et al. 2008) are better choices.

The selection of the filtering method heavily depends upon the type of neural signal to be extracted and the needs of the subsequent signal-processing steps to obtain this information. For example, if the desired signal is the population code, which can be obtained through analysis of the energy of the mass activity recorded by the neural interface, it may be sufficient to use a tightly defined band-pass filter centered on the maximum energy peak of the neural spectrum at approximately 1 kHz. However, if the desired signal is the rate code from an identified single unit, then the shape and timing of the single-unit waveform are essential and filtering techniques that retain the shape information of the unit, such as wavelet denoising, are appropriate.

Peripheral Nerve Signal Processing, Multipole Cuff Methods

Paul Yoo

Institute of Biomaterials and Biomedical Engineering, Department of Electrical and Computer Engineering, University of Toronto, Toronto, ON, Canada

Synonyms

Multi-array nerve electrode; Multi-contact nerve electrode; Multielectrode array

Definition

A method of obtaining motor or sensory information from the peripheral nervous system for the purpose of implementing closed-loop control of neuroprosthetic systems (e.g., functional electrical stimulation devices or electrical neuromodulation therapies).

Detailed Description

The peripheral nerve can consist of one or more bundles of nerve fibers (defined as a fascicle) that are tightly enclosed within a thin layer of connective tissue called the perineurium. The fascicle, in turn, is surrounded by the endoneurium, which is constructed from connective, collagen, and vascular tissue. As the nerve traverses distally from the spinal cord, the typically single (mono-fascicular) configuration of the peripheral nerve begins to diverge into multiple branches at various distal locations.

Due to this highly organized structure, the peripheral nervous system offers an attractive target for many neuroprosthetic devices that can include functional electrical stimulation (FES) systems for restoring lost neurological function or electrical neuromodulation therapies for treating chronic medical disorders. In contrast to

clinical applications that interface the central nervous system (e.g., deep brain stimulation), the peripheral nerve not only provides a minimally invasive target that can selectively activate specific neural pathways, but it also makes recording neural activity a potentially elegant solution for obtaining physiological information that can be used to control neuroprosthetic devices in a closed-loop fashion.

The Electroneurogram (ENG)

Ongoing electrical activity obtained from a peripheral nerve is commonly referred to as the electroneurogram (ENG). The reliable measurement of such activity is affected by the particular device used to interface with the nervous system and also by the manner in which the recorded signal is processed. The literature in this area of research indicates myriad factors that influence the quality of the recorded ENG: location of the recording electrode, configuration of electrode contacts, total number of recording sites, and sources of noise. Therefore, the objective of obtaining high-fidelity neural signals (i.e., large signal-to-noise ratio (SNR)) is critically dependent on both the optimal design of peripheral nerve interfaces and correspondingly effective signal-processing techniques.

Nerve Cuff Electrodes

Over the past several decades, various different types of electrodes have been developed for peripheral nerve recording. Among those, the nerve cuff electrode has been one of the most widely studied peripheral nerve interfaces. This design entails an insulating layer (i.e., nerve cuff) – consisting of silicone or polyimide – that completely encircles the nerve. Individual electrode contacts – typically constructed from platinum or iridium oxide – are embedded within the inner surface of the nerve cuff such that electrical coupling occurs at the external surface of the nerve. As demonstrated by long-term implant studies, this design provides a stable mechanical

substrate with minimal acute and/or long-term tissue damage (Larsen et al. 1998; Grill and Mortimer 2000; Romero et al. 2001).

Evolution of Multipole (Multi-contact) Electrodes

Recent advances in electrode fabrication technology and data-processing techniques have supported the development of multipole electrodes that can record differential neural activity generated by multiple ENG sources. The source (s) of ENG activity can range from an individual nerve fiber to an entire population of axons within a single nerve fascicle. The spiral nerve cuff electrode is an extensively studied type of nerve electrode, where the insulating layer is constructed such that, by default, the electrode cuff curls into a cylindrical shape (Romero et al. 2001; Rozman et al. 2000; Naples et al. 1988). This design allows for (1) a “self-sizing” cuff that adjusts to the diameter of the nerve, (2) an even distribution of electrode contacts around the circumference of the nerve, and (3) optimal spatial resolution for selectively recording multiple ENG sources.

The Flat Interface Nerve Electrode (FINE) is an alternative electrode design aimed at improving upon the performance of the spiral electrode (i.e., round cross section). It was envisioned that fascicles located near the center of a circular nerve trunk could be better accessed electrically by slowly reshaping the nerve into a flatter, rectangular cross section (Yoo and Durand 2005; Tyler and Durand 2002). Interestingly, recent work has shown that some peripheral nerves naturally exhibit flat or oval cross sections (i.e., reshaping mechanism may not be necessary), such as near the major branching point(s) of the hypoglossal, sciatic, and pudendal nerves.

Nerve Recording Technique: Artifact Suppression

Due to the close proximity of electrically active muscle tissue, the ENG obtained from peripheral

nerve electrodes are prone to contamination by muscle-derived signal artifacts. Although conventional band-pass filtering techniques can provide modest improvements in the signal-to-noise ratio (SNR), a quasi- or pseudo-tripolar electrode recording technique has been used as a highly effective solution (Stein et al. 1975). This technique was originally described as involving three circumferential electrode contacts equally spaced along the length of a nerve cuff electrode. The two contacts located at the either end of the nerve cuff electrode are electrically shorted, and thus, the ENG is obtained by recording the difference in electrical potential between the two shorted electrode contacts and the remaining middle contact. By modifying the contacts at both ends of the nerve electrode, the pseudo-tripolar configuration can further attenuate any externally generated artifact that would otherwise produce a linearly varying signal along the length of the cuff (Rahal et al. 2000a, b; Andreasen and Struijk 2003). This technique can be applied to any multipole nerve cuff electrode.

Intrafascicular Electrodes

An intrafascicular electrode denotes a type of neural interface, where the electrode contact (s) is located within a nerve fascicle and therefore gains direct physical contact with nerve fibers. Despite the invasive nature of this electrode design (i.e., compromised perineurium), it can achieve remarkably superior ENG recordings compared to that of conventional nerve cuff electrodes. Examples range from single-channel wire-based electrodes, such as the longitudinally implanted intrafascicular electrode (LIFE) (Lawrence et al. 2003; Lefurge et al. 1991), to multielectrode arrays (MEA) such as the Utah Slanted Electrode Array (USEA), which consists of 100 needle-shaped electrodes (Branner et al. 2004). It is important to note, however, that effective long-term use of intrafascicular electrodes has yet to be demonstrated.

Information Content of Neural Activity

Inasmuch as the physical design of an electrode determines the quality and quantity of the recorded ENG activity, the method by which the electrical signals are subsequently processed is equally important for extracting physiologically relevant information.

Changes in ENG Activity

The most basic approach to processing ENG activity is to apply a band-pass filter (e.g., 1–2 kHz) that can isolate the frequency components most relevant to neural activity. The filtered signal can then be rectified, integrated, binned (e.g., several millisecond windows), and compared to a predetermined threshold value. Processed ENG data can be further applied to sophisticated computational approaches, such as artificial neural networks (Micera et al. 2001) or models that analyze the variance of the rectified-integrated signal to determine any statistically significant changes in ENG activity (Kurstjens et al. 2005). Further refinement of the recorded ENG can be achieved by characterizing the signal and noise components. This can involve subspace decomposition methods that use statistical information (e.g., higher-order statistics) about particular segments of the signal (Upshaw and Sinkjaer 1998). This approach is suitable for whole nerve recording, where a simple “on-off” signal is sufficient as a feedback signal.

Analysis of Mixed Signals

However, in many cases, the nerve can consist of multiple fascicles that convey a multitude of functionally disparate information. One may be interested in selectively recording from only one particular fascicle or from multiple sources of neural activity. To this end, mixed signal algorithms such as blind source separation (BSS) are an effective tool for processing ENG recordings. This approach is particularly attractive as the algorithm depends on statistical independence, and

not on any modeled estimate of each recorded signal. Traditional approaches – such as inverse problem algorithms – can provide very precise estimates of multiple sources, but require significantly more computational time, whereas beamforming (spatial filter) algorithms strike a good balance between computational speed and precision of source localization. Although numerous studies have validated these signal-processing algorithms using ENG activity obtained from multipole nerve cuff electrodes (Teshfayesus and Durand 2007; Zariffa et al. 2011; Wodlinger and Durand 2011), further work is needed to determine feasibility for long-term clinical use.

Future Direction

In summary, the use of peripheral nerve activity obtained from multipole electrodes holds much promise as an effective means of clinically implementing closed-loop control strategies in neuroprosthetic and neuromodulation systems. Despite the important advances that were highlighted in this very brief overview, an optimum solution for reliably obtaining information from the peripheral nervous system remains to be determined.

Peripheral Nerve Signal Processing, Source Localization

Brian Wodlinger

Department of Physical Medicine and Rehabilitation, University of Pittsburgh, Pittsburgh, PA, USA

Detailed Description

Background

Peripheral nerve trunks are composed of many individual nerve fibers (axons) which are segregated into several fascicles. The axons grouped in each fascicle tend to share a common peripheral endpoint, making them anatomically, if not functionally, distinct from those in other fascicles. This suggests that it may be feasible to identify the fascicles from which activity recorded by nerve cuff electrodes originates. For example, given several fascicles terminating separately in extensor and flexor muscle groups, this localization and subsequent separation of signals travelling to these groups could allow the control of prosthetics in people with amputated limbs.

Techniques

Techniques for source localization and separation in peripheral nerves are similar to those in other areas of biomedical signal localization and separation, such as EEG/MEG and ultrasound. These techniques are often referred to as beamforming (or spatial filtering) from ultrasound theory where transmit and/or receive beams of the device are steered and focused to provide added sensitivity in a given spatial location. Techniques may be nonadaptive, in that they only use an a priori model (often finite element based) of the geometry and physics of the situation, or adaptive, in the sense that they also use information from the recorded signals. Three applications of these techniques to the peripheral nerve case are discussed below.

Pathway-Level Beamforming

Zariffa et al. (2009; Zariffa and Popovic 2009) used a very general experimental lead field approach to generate classifiers for various combinations of activity. For example, by stimulating the various branches of the sciatic nerve intraoperatively, they were able to build a classifier that could classify compound action potentials based on their branch of origin. Equation 1, below, is used to estimate the source signals:

$$s = (H^T H)^{-1} L^T [L(H^T H)^{-1} L^T + \lambda I]^{-1} o \quad (1)$$

where s is the vector of source signal estimates, L is the lead field matrix, H is a reweighting matrix based on the weighted minimum-norm technique, λ is a regularization parameter for Tikhonov regularization (Tikhonov and Arsenin 1977), and o is the vector of observed voltages on each contact of the electrode. Focusing on “pathway” rather than “fascicle” restricts the problem to the components we are able to stimulate, potentially providing more functionally useful distinctions, but is shown to have difficulty when multiple branches are active simultaneously.

Fascicle-Level Beamforming

Fascicles are each surrounded by a thin membrane known as the perineurium. Unlike the epineurium which forms the loose outer connective tissue of the nerve, the perineurium constitutes the equivalent of the blood-brain barrier in the peripheral nerve and is composed of tight junctions making it higher impedance. This high-impedance membrane makes signals originating from the same fascicle difficult to distinguish but helps to separate signals originating in distinct fascicles.

Wodlinger and Durand (2009, 2011) propose and validate a technique to achieve separation of both large compound action potential-type signals and artificially generated noise-like fascicular level signals in an *in vivo* rabbit model. Figure 1 provides an example of using this algorithm to

both separate mixed fascicular signals and identify the fascicles of origin. A finite element model was used to generate the lead field matrix L , which was then used to calculate the “transformation matrix” (M) of filters for each pixel (i) as in (2) and (3):

$$LM_{:,i} = \delta_i \quad (2)$$

$$M_{:,i} = \frac{LM_{:,i}}{\|LM_{:,i}\|} \quad (3)$$

Images of activity within the nerve could then be produced by multiplying the vector of observed signal on each contact, O , by the transformation matrix, M . Sources were then localized from the resulting images, either manually or through automated image analysis. The iterative technique comprised of (4) and (5) below was then applied to optimize filters for the sources (fascicles) present in the nerve:

$$f_i^n \rightarrow f_i^{n+1} = S_i^T M \quad (4)$$

$$\begin{aligned} S_i^n &\rightarrow S_i^{n+1} \\ &= S_i - \sum_{(j|j \neq i)} (M f_i^T)^T S_j (S_j - S_i) \end{aligned} \quad (5)$$

where S is the source location image, created initially using $S_i = OM_i$, and f is the filter for each source. Iterations were stopped when there was no improvement in the signal-to-interference ratio or a predefined threshold was reached. Overall, the technique separated tibial and peroneal signals from recordings on the main sciatic trunk with an RMS error of $14 \pm 10\%$ of signal mean.

Adaptive Beamforming

Adaptive beamforming techniques use information about which sources are currently active to adjust their filters or lead field model to improve accuracy. In this way, the iterative portion of the technique described above may be considered adaptive if the calculation was repeated at each timestep depending on which sources had been

Peripheral Nerve Signal Processing, Source Localization, Fig. 1 Separation of peroneal and tibial components from cuff recording on rabbit sciatic nerve using beamforming filters. (a) The mean of all 16 channels (for clarity) for a signal created by adding a normalized recording during tibial stimulation with a normalized recording during peroneal stimulation. The beamformers were applied to this signal to generate an estimate for each branch, shown in (c, e) (recovered signal). The equivalent single-branch signals (calculated by applying the filters to

the single-branch recordings directly) are shown for comparison in (b, d). Aside from some cross talk in (e), the separation is nearly complete. (f) Histology from this experiment overlaid with the location estimates of the tibial and peroneal sources and placed approximately within a schematic of the cuff electrode. Histology confirms that the fascicles overlaid by the beamforming location estimate correspond to the correct branches of the nerve. (Figure and caption are from Wodlinger and Durand 2011)

active (and the ratio of their activities) in the previous timestep. Many other adaptive techniques exist, including the hierarchical method described in Calvetti et al. (2011) and an adaptation of the CHAMPAGNE technique (Tang et al. 2012).

Current State of the Art

Techniques which penetrate the nerve to record from particular pathways directly have already

enjoyed some success in animal and first-in-man studies (Micera et al. 2008, 2010; Dhillon et al. 2004; Dhillon and Horch 2005). The signal processing techniques presented here allow more useful signals to be harvested from less-invasive recording methods which may be more robust in the long term since the perineurium is not compromised by the electrode. Computational and acute animal studies have been completed by a number of groups (Zariffa et al. 2009; Zariffa and Popovic 2009; Wodlinger and Durand 2009, 2011; Calvetti et al. 2011; Tang et al. 2012),

demonstrating that these techniques effectively separate functionally or anatomically independent signals. Chronic animal and human studies to validate the general hypothesis of robustness are a subject of future work.

Peripheral Nerve Stimulation Technique, Nerve Block

Michael Ackermann¹ and Niloy Bhadra²

¹Stanford University, Stanford, CA, USA

²Case Western Reserve University, Cleveland, OH, USA

Synonyms

Direct current nerve block (DC block); Electrical nerve block; High-frequency nerve block; Kilohertz-frequency alternating current (KHFAC) nerve block

Definition

“Nerve block” is an electrical method of inducing block of the conduction of action potentials in peripheral nerves. This type of block can be obtained by three distinct methods: collision block, direct current (DC) block, and kilohertz-frequency alternating current (KHFAC) nerve block. Collision block stimulates the nerve at a rapid rate and uses antidromic annihilation of action potentials of interest. The clinical use of this technique is limited. DC blocks action potentials by two different mechanisms – depolarization block and hyperpolarization block – but typically damages the nerve within a few seconds. KHFAC block produces a rapid and reversible nerve block and is potentially safe for long-duration applications.

Detailed Description

Background

There is an unmet clinical need for a method for rapidly and reversibly blocking peripheral nerves. This will have potential applications in the treatment of motor, sensory, and autonomic conditions where the pathology is based on the overactivity of neural signals. Present clinical methods of

nerve block have many disadvantages including prolonged activation and reversibility times. KHFAC block offers many advantages and has been the subject of increased research interest over the last decade.

Characteristics of KHFAC Nerve Block

KHFAC nerve block was initially investigated in amphibians (Tanner 1962) and later in mammals, using frequencies of 100 Hz–10 kHz, demonstrating nerve block for frequencies greater than 4 kHz (Bowman and McNeal 1986). Recently it has been conclusively demonstrated that KHFAC can be used to quickly, repeatedly, and reversibly block conduction in the peripheral nerves (Kilgore and Bhadra 2004; Tai et al. 2004; Bhadra and Kilgore 2005; Kilgore and Bhadra 2013 [review article]). KHFAC nerve block has been tested in multiple mammalian *in vivo* models, including rat, cat, dog, and monkey.

An example of the typical experimental results using KHFAC nerve block is shown in Fig. 1. KHFAC neural conduction block can occur as quickly as 50 ms. KHFAC block can be reversed simply by turning the high frequency off, and in most cases, the nerve returns to normal conduction in less than a second (Bhadra and Kilgore 2005). It is possible to obtain a graded/partial

HFAC neural conduction block by using amplitudes which are less than the block threshold (minimum current required to completely block a nerve) (Bhadra and Kilgore 2005). The most ideal block characteristics are found at frequencies in the range of 10–40 kHz delivered through electrodes that surround the nerve (nerve cuff electrodes).

KHFAC nerve block characteristically has an initial short period of rapid firing, manifested as a large muscle twitch (the onset response) before the block is established (Bhadra and Kilgore 2005). This onset response is affected by a large number of variables and has been intensely investigated. Multiple methods have been established to reduce or eliminate the onset response.

Mechanisms of KHFAC Nerve Block

There are two modern hypotheses about the mechanism of KHFAC block. One, based on computer simulations, suggests that elevated potassium levels cause block. The other hypothesis, based on computer simulations along with some experimental data, suggests that the mechanism of the KHFAC-induced conduction block is a depolarization-induced sodium channel inactivation (Ackermann et al. 2011).

Peripheral Nerve Stimulation Technique, Nerve Block, Fig. 1 KHFAC block of the rat sciatic nerve at 30 kHz. A test stimulus at 0.5 Hz is delivered proximally to generate supramaximal gastrocnemius muscle twitches, (2–43 s). KHFAC block is delivered from 7 s (red bar), blocking conduction. Initially the KHFAC produces a large

activity, the “onset response.” After the onset, the nerve is fully blocked. After 30 s of KHFAC delivery, the block is turned off (at 37 s) and twitches due to the test stimulation return instantly. The muscle twitches before and immediately after block are identical (dashed line), showing the instantaneous reversibility of this method

Clinical Investigations

Three commercial entities are pursuing systems based on KHFAC block for obesity control (EnteroMedics), spinal cord stimulation for chronic pain (Nevro), and reduction of pain from amputation neuromas (Neuros Medical).

Peripheral Nerves, Anatomy and Physiology of

Mario Romero-Ortega

Bioengineering Department, The University of Texas at Dallas, Richardson, TX, USA

Surgery Department/U.T. Southwestern Med. Center, Dallas, TX, USA

U.T. Arlington Research Institute, Fort Worth, TX, USA

Definition

Peripheral nerves are formed by axonal extensions of neurons in the dorsal root ganglia and spinal cord (spinal nerves), brain stem (cranial nerves), or sympathetic and parasympathetic

ganglia (autonomic nerves) that connect the central nervous system (brain and spinal cord) with the rest of the body to maintain homeostasis, mediate sensation, movement, and coordination. The 43 pairs of sensory and motor nerves in the human body are composed of bundles of axons embedded in a collagenous matrix (endoneurium), ensheathed by connective tissue (perineurium), and wrapped by an external connective layer (epineurium). The cellular components of peripheral nerves include Schwann cells, fibroblasts, endothelial-like cells, and macrophages (Stewart 2003).

Detailed Description

Types of Peripheral Nerves

Peripheral nerves are also classified in reference to the main function that they serve, as either motor sensory or autonomic nerves.

Motor Nerves

This nerves are composed by fibers elongating from motor neurons in the ventral spinal cord and brain stem, and innervate skeletal muscle, visceral smooth muscle, cardiac muscle, or glands. Motor neurons are further subdivided into alpha (α) and gamma (γ) neuron types. The alpha motor axon and its associated muscle fiber constitute a motor unit. Action potentials traveling on motor neurons convey intent and magnitude for muscle activation.

Sensory Nerves

Axons extending from the dorsal root ganglion (DRG) innervate sensory receptors in the skin, muscle, and joints. Sensory fibers transduce mechanical, chemical, or thermal stimuli from specialized receptors in the skin and muscle into electrical signals and convey them to the spinal cord and brain for perception and appropriate response. Sensory neurons are classified by modalities: (i) proprioceptors for body position; (ii) mechanoreceptors for touch, pressure, and vibration; (iii) thermoreceptors for innocuous cold or warm temperatures; (iv) nociceptors for pain-inducing high-threshold stimuli; and

(v) puriceptors that respond to itch-inducing compounds.

Such receptors are innervated by sensory neurons in the DRG, which is formed by a heterogeneous cellular population including large myelinated proprioceptive neurons that express TrkC receptors that bind to neurotrophin 3 (NT-3) and medium-size mechanoreceptive neurons that bind to brain-derived growth factor (BDNF) and/or glial-derived growth factor (GDNF) via its respective TrkB and Ret receptors. Sensory neurons responsive to pain, temperature, and itch are either peptidergic neurons expressing TrkA receptor that binds to nerve growth factor (NGF) and neuropeptides such as calcitonin gene-related peptide and substance P, or non-peptidergic neurons expressing Ret receptors and expressing the isolectin B4.

Autonomic Nerves

These nerves are formed by axons from the sympathetic and the parasympathetic paravertebral ganglia. Autonomic nerves convey information from the medulla, pons, and hypothalamus to organs and glands, and participate in the involuntary control of heart rate, digestion, respiration, salivation, perspiration, pupillary dilation, urination, and sexual arousal. Postganglionic axons release acetylcholine (parasympathetic) or norepinephrine (sympathetic) neurotransmitters to control their target organs.

Physiology

Neurons transmit information via waves of membrane depolarization known as action potentials (APs). Sodium channels open after strong stimuli which cause membrane depolarization and the generation of APs. Potassium channels are involved in repolarization of the axon membrane. In myelinated axons, both Na and K channels are concentrated at the nodes of Ranvier and mediate saltatory nerve conduction. Myelinated axons conduct APs at a rate of up to 120 m/s, whereas unmyelinated fibers conduct at a rate of 2–4 m/s (Krarup et al. 1988). Non-painful touch of the skin is sensed by low-threshold

mechanoreceptors (LTMRs), which are classified as A β -, A δ -, and C-LTMRs according to their action potential conduction velocities. In the glabrous skin, A δ afferents are rapid-adapting (RA) neurons that innervate the Pacinian and Meissner's corpuscles, which are vibration receptors that encode texture. The highest spatial acuity of mammalian touch receptors provides object features such as edges and curvature and involve A β afferents innervating Merkel receptor cells.

PNS Injury and Regeneration

Each year, approximately 360,000 people in the United States suffer a peripheral nerve injury (PNI), which is a leading cause of lifelong disability (Kelsey et al. 1997; Taylor et al. 2008). Peripheral nerve injuries result in paralysis, sensory loss, and lack of autonomic control distal to the injury site.

Cellular Response to Injury

Axonal injury results in disruption of target-derived trophic factors normally conveyed to the soma by axonal transport. If the axon is transected, sodium and calcium diffuse into the injured axoplasm triggering action potentials. Both of these events result in the dispersal of Nissl substance that labels rough endoplasmic reticulum (chromatolysis) and upregulation of transcription factors including Atf3, c-Jun, Stat3, and Sox11, which activate a number of different signaling pathways including the MAPK/JNK/ERK, the AKT/p38, and the JAK/STAT/mTOR (Kiryu-Seo and Kiyama 2011). These changes result in increased TrkA and TrkB expression. Conversely, neurofilaments, neurotransmitters, and postsynaptic receptors are downregulated (Patodia and Raivich 2012).

Wallerian Degeneration

Severe injury to the nerve results in Wallerian degeneration, a process of degeneration of nerve fibers distal to the injury site through the infiltration of macrophages, which clear myelin debris and reutilize its lipid content for regeneration and remyelination. The upregulation of c-Jun in

Schwann cells has been shown to be a key regulator of Wallerian degeneration by inducing the expression of trophic factors and adhesion molecules, the formation of endoneurial tubes or bands of Büngner, and promoting myelin clearance (Fawcett and Keynes 1990).

Spontaneous Axonal Regrowth

Transected nerves in which the gap between the proximal and distal stumps is less than 1 cm apart regenerate from the proximal into the distal stump spontaneously. The transected axon swells, increases production of mitochondria and microtubules, and extends 6–10 collateral branches down the endoneurial tubes of the distal segment. The rate of elongation is 3–4 mm/day after crushing and 2.5 mm/day after sectioning the nerve (Fugleholm et al. 1994). Regenerating axons are 1–2 μm in diameter and enlarge in the 2–6 months after reinnervating their targets (Navarro et al. 1994). The environment through which axons regenerate consists of Schwann cells, and their basal lamina contains primarily laminin, fibronectin, and collagen. It has been demonstrated that without the Schwann cells, either axonal regeneration fails or axonal growth is compromised.

Guidance Molecules

Nerve injury leads to the upregulation of neurotrophic factors and their receptors in the degenerating nerve segment and in the denervated end targets, including neurotrophins such as nerve growth factor (NGF), BDNF, NT-3, and NT-4 (Carroll et al. 1998; Chen et al. 2002). Nerve regeneration is known to respond to concentration gradients of guidance molecules which orient axonal outgrowth toward the denervated target (Zheng and Kuffler 2000). The regenerative path of adult motor neurons in the spinal cord and sensory neurons in the DRG can be controlled by specific growth factors. Specifically, the induced expression of NGF has been shown to guide the regenerative path of DRG axons both into the spinal cord and in the periphery (Romero et al. 2001; Hu et al. 2010). In addition, delivery of growth factors such as BDNF and GDNF has been shown to enhance nerve regeneration and

functional recovery in a rat model of delayed nerve repair (Gordon 2009).

Accuracy of Regeneration

Injured nerves are capable of reinnervating their original targets; however, this process is not without errors. Axonal regeneration is more accurate following crush compared to transection injuries as regenerating axons usually grow along their parent tubes and are guided directly back to their targets (Brown and Butler 1976). If the nerve is transected, regenerating sprouts can enter inappropriate tubes in the distal stump ending in aberrant targets. The expression of the peptide L2/HNK1, NCAM and polysialic acid in the regenerative motor axons, and the release of trophic factors by the distal stump are thought to influence selective reinnervation, and pruning of axons that reinnervate erroneous targets contributes towards the specificity of nerve regeneration (Madison et al. 1996; Eberhardt et al. 2006).

Remyelination

Schwann cells dedifferentiate from myelinating to regenerative types after injury and participate in nerve regrowth and remyelination. Remyelination requires the axonal release of neuregulin-1 type III to instruct the Schwann cells; however, this process does not completely restore myelin thickness to pre-injury levels, and axons remain long-term hypomyelinated (Schroder 1972). The distance between internodes is also smaller than normal, usually around 400 μm , which may explain the lower conduction velocities of regenerated nerve fibers (Burgess and Horch 1973; Hildebrand et al. 1985).

Nerve Repair

Primary tensionless end-to-end attachment of a completely severed peripheral nerve is the preferred method of nerve repair as it mediates partial nerve regeneration and functional recovery. If the gap is too long for a tensionless reattachment, the recommended “gold standard” is the use of autologous nerve grafts to bridge the gap defect. However, donor site morbidity, scarce number of usable donor nerves, and suboptimal functional recovery drastically limit this alternative (Zochodne 2012).

Allogenic or xenogenic nerve grafts have been proposed but require immunosuppression to prevent graft rejection. Decellularized nerve allo-/xenografts have also been investigated, but the functional recovery achieved is limited. Clinical alternatives in the form of simple hollow tubes made of biosynthetic materials (i.e., polylactic-coprolactone, polyglycolic acid, type I collagen) are currently FDA-approved and commonly used for reconstruction of short peripheral nerve injuries. Synthetic materials continue to be developed in order to improve the functional efficacy of biosynthetic nerve guides in nerve repair (Pfister et al. 2011). Simple tube nerve repairs are, however, inferior to nerve autografts and decellularized allografts, presumably due to the lack of endoneurial microstructure of conduits which in turn results in the clustering of regenerating fibers. Luminal fillers such as polyamide filaments, collagen filaments, polyester filaments, PGA filaments and gelatin fibers, and multi-luminal microchannels have shown promising results (Tansey et al. 2011).

Limitations in PNS Regeneration

The causes of unsuccessful repair include failure of axons to regenerate after chronic axotomy and innervation of incorrect targets. The first leads to weakness and poor sensory recovery since axons connect to inappropriate regions of the skin, leading to qualitatively abnormal and poorly localized sensation, and the second to poor muscular control as muscles receive inputs from axons originally connected to different muscles. Furthermore, spontaneous nerve regeneration proceeds through short but not long nerve gap defects (Hoke and Brushart 2010).

Definition

Vestibular End Organ

The vestibular end organ is located in the inner ear next to the cochlear of the auditory system. The end organ comprises two components. The three semicircular canals, which are roughly orthogonal, sense rotational head movement while the two otolith organs (utricle and saccule), which are also orthogonal, sense linear head acceleration.

Processing

Signals from the vestibular end organ carry head velocity and acceleration information that is

modified at the level of the brainstem to control the eye movements that stabilize vision when the head moves (vestibuloocular reflex) and to control the muscles that control posture and balance (vestibulospinal reflexes).

Detailed Description

Sensory System

The vestibuloocular reflex (VOR) is mediated by the six semicircular canals and four otolith organs (horizontal, anterior and posterior canals, and the utricle and saccule from both inner ears). The canals are arranged in such a way that each canal on the left side has an almost parallel counterpart on the right side. Each of these three canal pairs work in a *push-pull* fashion. When one canal is stimulated, its corresponding partner on the other side is inhibited, and vice versa. This push-pull system makes it possible to sense all directions of rotation. For example, while the *right horizontal canal* gets stimulated and sends the dominant signals to the central vestibular system during head rotations to the right, the *left horizontal canal* gets stimulated during head rotations to the left. Vertical canals (the anterior and posterior canals) are coupled in a crossed fashion, for example, head rotations that are excitatory for an ipsilateral anterior canal are inhibitory for the contralateral posterior canal, and vice versa. At one end of each semicircular canal, the canal expands forming a bulbous structure, the ampulla. Within the ampulla there is a saddle-shaped structure, the crista ampullaris, which consists of a ridge of sensory hair cells (Landolt et al. 1975). The cupula extends across the ampulla, forming a tight hydraulic seal around the internal wall of the ampulla (Dohlman 1971; Lim 1973). During head motion the inertia of the endolymph fluid within the canal causes the cupula to bend, thereby stimulating the sensory hair cells.

The otolith organs comprise the saccule and utricle. They are sensitive to gravity and linear acceleration. The maculae of these organs are an array of hair cells that have their cilia embedded in a gelatinous matrix, dense with calcium carbonate crystals, that floats in viscous endolymph fluid.

Deflection of the dense matrix during head acceleration stimulates the hair cells and afferent nerves. Due to their orientations in the head, the utricle is most sensitive to horizontal head movement, whereas the saccule is sensitive to vertical head movement.

There are two types of sensory hair cells, type I and type II (Wersall 1956). In the canals, type I hair cells are concentrated on the central zone of the crista ampullaris, whereas type II hair cells lie mainly on the peripheral zone (Spoendlin 1966; Lindeman 1969; Tsuji et al. 2000). In the otolith organs, type I hair cells are located near the midline (striola) of the macula, whereas type II hair cells are further from the striola. Type I and type II hair cells are morphologically distinct. The Type I has a calyx (cuplike) structure that surrounds the hair cell, whereas the type II has a bouton (knob-like) structure that forms a synapse with a vestibular afferent.

Sensory Signals

Vestibular *afferents* can receive synaptic input from one or both hair cell types. Some 20% of afferents have type I input only, 10% type II input only and 70% dimorphic (both type I and II) input. The variation in the inter-spike interval of an afferent's background discharge rate defines its regularity. A low variation (normalized coefficient of variation [CV^*] < 0.1) indicates regular, and a high variation (CV^* > 0.1) indicates irregular (Goldberg et al. 1984). Vestibular afferents that get most of their synaptic input from the central zone of the crista ampullaris, where type I hair cells are concentrated, are predominantly irregular in their resting discharge rate. Afferents that arise from the peripheral zone, where type II hair cells are concentrated, are predominantly regular in discharge rate (Baird et al. 1988). Taken together these findings suggest that type I hair cells mediate irregular discharging afferents, whereas type II hair cells mediate regular afferents.

Vestibular *efferents* project to the peripheral vestibular organs, where they innervate the vestibular neuroepithelium extensively (Lindeman 1969). The innervation pattern in the periphery is diffuse with individual efferent fibers terminating onto multiple hair cells and afferent fibers that

Peripheral Vestibular Signal Processing, Fig. 1 Vestibular efferents terminate on type I afferents (with excitatory effects) and type II hair cells (inhibitory) and their afferents (excitatory)

innervate the vestibular end organs (see Fig. 1). Specifically, efferent terminals make direct contact with vestibular type II hair cells, and evidence in non-mammals suggests they have inhibitory effects. In contrast, efferent terminals do not contact type I hair cells directly, due to the surrounding calyx terminal. Rather, efferent terminals contact the outer surface of the calyx and the parent axon and have strong excitatory effects in mammals (Goldberg and Fernández 1980).

Signal Processing

Models of the VOR in the alert monkey have suggested a highly modifiable (phasic) component of the reflex (Lisberger and Pavelko 1986; Lasker et al. 1999; Minor et al. 1999). This phasic component is probably mediated by irregularly discharging vestibular afferents that predominantly encode head acceleration, rather than regularly discharging afferents that have relatively linear encoding of head velocity between 2 and 20 Hz (Hullar and Minor 1999). This phasic component has high sensitivity, and so is large during

excitation, but can rapidly go into cutoff (negative saturation) during inhibition. In contrast, the less modifiable (tonic) pathway that is probably mediated by regular afferents has little susceptibility to inhibitory cutoff. The phasic component appears to be responsible for most of the increase in VOR response that occurs for contexts such as lens magnification (Clendaniel et al. 2001) and during near viewing (Lasker et al. 2002; Migliaccio et al. 2004, 2008).

The flocculus of the vestibulocerebellum plays an important role in partially restoring the amplitude and symmetry of the VOR after a large injury to one of the two balance organs (e.g., Babalian and Vidal 2000). The Purkinje cells in the flocculus participate in adjusting the VOR during viewing contexts that require fast changes in response, e.g., during near viewing (Lisberger and Fuchs 1978; Snyder and King 1996). The floccular target neurons (FTN) receive input from both the flocculus and primary vestibular afferents and are thought to be important for VOR adaptation (Lisberger 1994; Blazquez et al. 2006). The modulation changes of FTN neurons correspond with changes in the VOR response induced by training with visual-vestibular conflict (Lisberger 1994; Lisberger et al. 1994a, b; Galiana and Green 1998). Thus they appear to make a major contribution to VOR adaptation and calibration.

Definition

Peripheral vision differs significantly from foveal vision. Models of peripheral vision attempt to

capture these differences mechanistically and/or predict task performance arising from these differences. Visual acuity, contrast sensitivity, color vision, and motion perception all vary with eccentricity, i.e., with distance from the center of gaze. However, a more consequential difference concerns peripheral vision's degradation in the presence of clutter, a set of phenomena known as crowding. A dominant, biologically inspired, model of crowding hypothesizes that peripheral vision encodes its inputs in terms of a rich set of local summary statistics. This pooling model of crowding has similar architecture to standard feed-forward hierarchical models of vision, and to convolutional networks, with the most notable difference being that pooling occurs over sparse, sizeable regions that grow linearly with eccentricity. Coarse encoding as a function of eccentricity leads to substantial confusions and ambiguities, which in turn provides a strong constraint on performance of many visual tasks.

Detailed Description

The visual field, the entire spatial scope of vision, subtends approximately 180° horizontally and 120° vertically (Traquair 1927). Less than 1% of the visual field lands within the fovea, i.e., the central rod-free area of the retina, subtending approximately 1.7° of visual angle in diameter. Peripheral vision refers to visual processing of the rest of the visual field and has considerable loss of information relative to the fovea. This begins at the retina, which employs variable spatial resolution to get past the bottleneck of the optic nerve. However, it does not end there, but rather continues into visual cortex, where foveal representation receives approximately half of the available cortical resources (Tootell et al. 1982). The reduced density of photoreceptors coupled with reduced cortical resources leads to reduced ability to resolve high spatial frequencies with increasing distance from the point of gaze. Acuity (the ability to resolve fine details) diminishes approximately linearly with eccentricity, over a fairly wide range of eccentricities. Data-driven models of peripheral acuity have simply approximated, e.g., the spacing necessary to

resolve a grating, or the letter size necessary for recognition, as a linear function of eccentricity (Levi et al. 1985; Anstis 1974). Additional models have approximated the area of the brain dedicated to processing 1° of visual angle as a function of eccentricity, known as the cortical magnification factor (Horton and Hoyt 1991; Strasburger et al. 2011). Image processing-based models have captured both the information loss due to reduced acuity and changes in the contrast sensitivity function by filtering the input stimulus as a function of eccentricity to remove subthreshold spatial frequency content (Anstis 1998; Geisler and Perry 1998).

Reduced peripheral acuity has only a tiny effect, compared with peripheral vision's sensitivity to clutter, known as visual crowding. At its core, crowding is the inability to identify an object in the periphery when there are others in proximity; the objects can be detected but are difficult to identify (Levi et al. 2002). Korte (1923) described that in viewing peripheral text, firm localization of both the letters and their constituent elements was extremely difficult and error-prone (as discussed more recently in (Strasburger et al. 2011)). More generally, peripheral vision is locally ambiguous in terms of the phase and location of features. Observers have difficulty distinguishing 180 degree phase differences in compound sine wave gratings in the periphery (Bennett and Banks 1991; Rentschler and Treutwein 1985) and show marked position uncertainty in a bisection task (Levi and Klein 1986). Furthermore, such ambiguities appear to exist in processing of real-world objects and scenes, although we rarely have the opportunity to be aware of them; peripheral vision tolerates considerable image variation without giving us much sense that something is wrong (Freeman and Simoncelli 2011; Koenderink et al. 2012). Unlike acuity losses, which impact only tasks relying on quite high spatial frequencies, crowding occurs with a broad range of stimuli (Pelli and Tillman 2008). It is ever-present in real-world vision, where the visual system is faced with cluttered scenes full of objects and textures. Crowding constrains what we can perceive at a glance, which in turn constrains visual performance.

Modeling Crowding

Based on the phenomenology, a number of researchers have suggested that crowding might occur due to peripheral texture processing mechanisms. These ideas originated with Lettvin's suggestion of crowding as giving the observer only a statistical representation of the visual input (Lettvin 1976) and continued through more recent theories of crowding as "forced texture processing" (Pelli et al. 2004) and compulsory averaging (Parkes et al. 2001). Relatedly, other work has suggested that crowding arises from integration over large receptive fields (or "pooling regions") that grow with eccentricity (c.f., Flom et al. 1963; Levi et al. 1985; He et al. 1996; Bouma 1970). Such pooling over large regions is also reminiscent of texture processing mechanisms, presumed to compute summary statistics over sizeable regions of the visual field (Rosenholtz 2016). The most successful, biologically plausible, texture models have described texture using a rich set of image statistics (Heeger and Bergen 1995; Portilla and Simoncelli 2000; Gatys et al. 2015), suggesting that peripheral vision might also encode its inputs using a high-dimensional set of summary statistics (Rosenholtz 2016).

Balas et al. (2009) operationalized peripheral texture processing by suggesting that peripheral vision might compute texture statistics within sparse local pooling regions that overlap and tile the visual field. They suggested as a candidate set of image statistics those used in a state-of-the-art model of texture appearance (Portilla and Simoncelli 2000). Specifically, after a prefiltering stage that mimics acuity losses, the model computes, within each pooling region, the marginal distribution of luminance; luminance auto correlation; correlations of the magnitude of responses of oriented V1-like wavelets across differences in orientation, neighboring positions, and scale; and phase correlation across scale. Computing a given second-order correlation merely requires taking responses of a pair of V1-like filters, point-wise multiplying them, and taking the average over the local region. Freeman and Simoncelli (2011) provided the first full instantiation of this model in a form that could take as input a substantial portion

of the visual field. Balas, Rosenholtz, and others have studied this model extensively, calling it the Texture Tiling Model, or TTM (Keshvari and Rosenholtz 2016; Rosenholtz et al. 2012b).

The TTM mechanism has clear connections to standard models of hierarchical encoding for object recognition and to convolutional neural networks (Riesenhuber and Poggio 1999; Krizhevsky et al. 2017; Yamins et al. 2014). The proposed mechanism differs from standard models in two main ways: First, the nonlinearities used to compute second-order correlations do not match those in the standard object recognition models nor in convolutional neural networks. Second, standard object recognition models do pool the outputs of feature detectors, but the pooling regions tend to be small relative to the support of those feature detectors, and not to grow with eccentricity (Chen et al. 2017).

The rich, high-dimensional set of statistics encoded by TTM provides an efficient, compressed encoding. It preserves a great deal of useful information about the visual input and yet loses considerable information, precluding perfect reconstruction of the original stimulus. The ambiguities and confusions arising from this encoding appear to constrain performance at a wide range of visual tasks, from crowded peripheral object recognition (Balas et al. 2009; Rosenholtz et al. 2012b; Rosenholtz et al. 2012a; Keshvari and Rosenholtz 2016), through visual search (Rosenholtz et al. 2012b; Zhang et al. 2015; Chang and Rosenholtz 2016), to scene perception (Rosenholtz et al. 2012a; Ehinger and Rosenholtz 2016).

Though other models of peripheral crowding have been proposed and demonstrated to predict a subset of phenomena (Wolfe 1975; Krumhansl and Thomas 1977; Wilkinson et al. 1997; Parkes et al. 2001; Baldassi et al. 2006; May and Hess 2007; Greenwood et al. 2010; van den Berg et al. 2010; Nandy and Tjan 2012; Chaney et al. 2014), they have not been as extensively tested. Many of the alternative models are not image computable and as a result cannot easily be generalized to arbitrary visual inputs, making testing them prohibitive.

Limitations of Current Models and Future Paths

Pooling mechanisms of crowding are largely hypothesized to be feed-forward, whereas connections in visual cortex and throughout the visual system are not unidirectional. What, if any, role feedback mechanisms might play in crowding remains unclear (Clarke et al. 2014). Future models of peripheral vision will need to capture temporal aspects of the stimuli, such as motion or flicker, as well as the encoding of different information from the two eyes, such as binocular disparity. A number of questions also remain as to the pooled summary statistics: whether any statistics or feature detectors are missing from the model and whether more biologically plausible features might lead to better predictive power. In addition, given recent success of deep learning techniques to optimize the features measured by a computational neural network, questions also remain as to whether improved models might learn their features instead of using hand-coded image statistics.

Phase Models, Noisy

G. Bard Ermentrout
Department of Mathematics, University of
Pittsburgh, Pittsburgh, PA, USA

Definition

Neural oscillators can be reduced to simple one-dimensional models where the only variable is the time-like phase of the oscillator. If the inputs to the oscillator are small enough, this phase description remains valid even if the inputs are “noisy.” Using the noisy phase description of an oscillator allows us to do many otherwise difficult calculations. We review these calculations in this entry.

Detailed Description

Noise is ubiquitous in the nervous system and has been the subject of many experimental and theoretical studies (Laing and Lord 2009). Most of the techniques for analyzing the effects of noise depend on the use of very simple models such as the leaky integrate-and-fire model or other scalar models. Many neurons generate periodic firing (oscillations) when subjected to a tonic drive but because they are subjected to many uncontrolled environmental inputs, the oscillations are subjected to noise. In absence of any inputs a deterministic limit-cycle oscillator can be characterized by its *phase* which for simplicity we will take to

be the time since the last peak in the voltage. This is called the zero phase and if the limit cycle has a period T , then we identify the phase as $\theta = (2\pi/T)t$ where t is the time since the last spike. (The normalization of the phase is not necessary but is an intuitively appealing convention as the phase lies on the circle of radius 1.)

Before describing the phase of an oscillator in the presence of noise, we introduce an important concept, the *phase response curve* (PRC). The PRC describes the effect of a small perturbation of the oscillator (in the context of neurons, this is a brief current input, e.g., as in a synapse). That is, suppose that the perturbation occurred at a phase, θ (i.e., at t milliseconds after the last spike, where $\theta = 2\pi t/T$). This will cause the next spike to occur at some time $\hat{T}(\theta)$, whereas in absence of the perturbation, the neuron would have fired at T , the interspike interval. The change in phase as a consequence of this perturbation is (Kuramoto 1984)

$$\Delta(\theta) := \frac{2\pi}{T} (T - \hat{T}(\theta)).$$

The function $\Delta(\theta)$ is the PRC for the neuron and will be positive (negative) if the perturbation caused the neuron to spike earlier (resp. later) than it would have in absence of any inputs. As we will see shortly, the PRC is very useful in computing spike statistics, the effects of inputs, and the effects of coupling. Computing the PRC of real neurons can be as simple as perturbing the neuron with a square current pulse and measuring the change in the timing of the next spike. However, as no neuron is perfectly periodic (as there are many sources of uncontrolled noise), the computation of the PRC is rarely so easy and as such, there are many methods for trying to estimate it for real neurons (see Torben-Nielsen et al. (2010) for a review). See the entry ► [“Weak Coupling Theory,”](#) by Lewis for more details about the phase response curve.

When assessing synchrony between neurons, there are many metrics. In this entry, we will look at pairs of neural oscillators and compute the distribution of their phase difference. Typically, experimental neuroscientists do not have access to

the phase of a neuron (although there are methods to extract a “phase” from a voltage trace using the Hilbert transform (Stiefel et al. 2010)), but rather look at the cross-correlation, $CC(t_2 - t_1)$, of the spike trains. When the neurons are identical weakly perturbed oscillators, Pfeuty et al. (2003) showed that

$$CC(t_2 - t_1) := \frac{\langle S_1(t_1) S_2(t_2) \rangle}{\langle S_1(t) \rangle \langle S_2(t) \rangle} = P(2\pi(t_2 - t_1)/T)$$

$S_{j(t)}$ is the spike train and $P(\phi)$ is the density of the phase differences between the two neural oscillators. Thus, to assess cross-correlation, it is sufficient to study the phase-difference density. (This density is a normalized histogram of the phase differences between the two oscillators.)

Phase Reduction

A general asymptotically stable limit cycle with weak perturbations has the form:

$$\frac{dX}{dt} = F(X(t)) + \varepsilon G(t, X(t))$$

where $X' = F(X)$ has an exponentially stable limit cycle, $U(t)$, ε is a small parameter, and G is some perturbation. If we write $X(t) = U(\theta(t)) + \varepsilon Y(t)$, then

$$\frac{d\theta}{dt} = 1 + \varepsilon Z(\theta) \cdot G(t, U(\theta)) + O(\varepsilon^2) \quad (1)$$

In these coordinates, θ , the phase lies between 0 and T , the period. A suitable rescaling of θ will yield equations that are 2π periodic. The key object here is $Z(\theta)$ called the *adjoint function*, the unique T -periodic solution to

$$\frac{dZ}{dt} = -D_X F(U(t))^T Z, Z(t) \cdot \frac{dU(t)}{dt} = 1$$

The adjoint function is sometimes called the *infinitesimal PRC* or *iPRC*. For the rest of this entry, when I talk about the PRC, I mean the iPRC and not the shift due to a generalized stimulus. If X represents, say, the *Hodgkin-Huxley* equation, that is, $X = (V, n, m, h)$, then we can write $Z = (V^*, n^*, m^*, h^*)$ in components. The

component labeled V^* is linearly proportional to the infinitesimal phase resetting curve for the HH equation when perturbed by brief application of a current pulse. Thus, if the only inputs into your neural oscillator are currents applied to the voltage variable, the $G(t, U(\theta)) = [I(t, \theta)/C_m, 0, \dots, 0]$ (where C_m is the membrane capacitance) and Eq. 1 becomes

$$\frac{d\theta}{dt} = 1 + \varepsilon \Delta(\theta) I(t, \theta) / C_m \quad (2)$$

We have dropped the higher-order terms in ε and replaced the voltage component of the adjoint with the iPRC which can be estimated for neurons. The beauty of Eq. 2 is that, with certain technical assumptions (Teramae et al. 2009), it holds even if the current includes a broadband noisy signal. (In the case where the noise is delta correlated, there is an additional term of the form $-\varepsilon^2 \Delta(\theta) \Delta'(\theta)$ which does not contribute much when ε is small (Teramae and Tanaka 2004; Teramae et al. 2009).) Equation 2 will be the focus of the rest of this entry. We will use it to compute various effects of noise on the oscillator and also to relate it to some common statistical measures of neurons.

Statistical Properties

Henceforth, we will rescale time in such a way that the unperturbed period of the oscillator is 2π and the frequency is 1. Let us replace the current in Eq. 2 by a noisy current, $\eta(t)$, that has zero mean and correlation, $C(\tau) := \langle \eta(t) \eta(t - \tau) \rangle$. For example, if η is a white noise process (or say an Ornstein-Uhlenbeck (OU) process), then $C(\tau) = \delta(\tau)$ (or for the OU process, $C(\tau) = \gamma \exp(-\gamma|\tau|)$). (In some cases, the OU process is scaled so that $C(\tau) = \exp(-\gamma|\tau|)$.) (Note that an OU process is the solution to the stochastic equation, $dx/dt = -x/\tau + \xi(t)/\sqrt{\tau}$ where $\xi(t)$ is a white noise process.)

The first question that arises is whether the noise affects the frequency of the neuron. Goldobin et al. (2010) provide a simple formula for the correction of the natural frequency (Ω):

$$\Omega = 1$$

$$+ \varepsilon^2 \int_0^{2\pi} \Delta'(\phi) \int_0^\infty C(s) \Delta(\phi - s) ds \, d\phi \quad (3)$$

The second part of the expression also involves additional terms (not shown) whose size is proportional to $1/K$ where K is proportional to the rate of attraction to the limit cycle. For strongly attracting limit cycles, K will be big. If the noise is white, then the correlation, $C(t)$, is a Dirac delta function and the second term vanishes. Thus, with white noise, the mean frequency is barely affected.

The noise causes jitter in the spike times which are equivalent to a slow diffusion of the phase. That is, the mean value of the phase is very weakly perturbed by the noise (cf. the above formula), but there will be a systematic drift equivalent to a random walk in phase. The phase reduction lets us compute the diffusion coefficient (D):

$$D = \varepsilon^2 \int_0^{2\pi} \int_0^\infty \Delta(\phi) \Delta(\phi + s) C(s) ds \, d\phi. \quad (4)$$

For white noise, ($C(\tau) = \delta(t)$), we see that the diffusion is proportional to the integral of the square of the iPRC. That is, the larger the iPRC (e.g., the more sensitive the neuron is to perturbations), the larger will be the diffusion and hence a noisier neuron. The interspike interval histogram can be approximated as a Gaussian centered at T with a width proportional to $\sqrt{(2D)}$. We should also remark that near bifurcations of the limit cycle, the iPRC will be very large and thus, as expected, very sensitive to noise.

Noise makes the estimate of the iPRC subject to measurement errors as well. As the effects of noise on the period of the oscillator are very small (cf. Eq. 3), the mean of a noisy iPRC is the same as the deterministic iPRC. However, the variance depends strongly on the noise and, furthermore, it is phase dependent. Ermentrout et al. (2011) compute this phase dependence for the case of weak white noise. With noise of amplitude ε and a perturbation of magnitude β occurring at phase ϕ in the cycle, the variance (Var) is

$$\text{Var}(\phi) = \varepsilon^2 \left(\int_0^{2\pi} \Delta^2(s) ds + 2\beta \Delta'(\phi) \int_0^\phi \Delta^2(s) ds + \int_\phi^{\phi+\beta\Delta(\phi)} \Delta^2(s) ds \right)$$

Suppose that we create a frozen noisy signal (one which we can exactly repeat) and we apply it to the same neuron over multiple trials. If there are no other sources of noise to the neuron, then over time, even though the neuron starts out at different states, the trials will eventually line up. If there is a small amount of independent noise, then the trials will nearly line up (Mainen and Sejnowski 1995) but will have some jitter. The rate at which the trials line up is exponential with exponent, λ_0 . Figure 1 shows this phenomena for a pair of HH neurons driven with a current of $10 \mu\text{A}/\text{cm}^2$ and noise of amplitude $\varepsilon^2 = .0625 \text{ mV}^2/\text{ms}$. The left panel shows the voltage difference as a function of time and the right shows the evolution of the phase difference for the phase-reduced pair. The inset shows the iPRC of the HH equations. Goldobin et al. (2010) compute λ_0 , called the *leading Lyapunov exponent* for the phase-reduced system:

$$\lambda_0 = -\varepsilon^2 \int_0^{2\pi} \Delta'(\phi) \int_0^\infty \Delta'(\phi - s) C(s) ds \, d\phi. \quad (5)$$

Note that with white noise, $\lambda_0 = -\varepsilon^2 \int_0^{2\pi} [\Delta'(\phi)]^2 d\phi$. Abouzeid and Ermentrout (2009) showed that for smooth iPRCs with a fixed diffusion, D , the iPRC that makes this exponent most negative with white noise is $\Delta(\phi) = -\sin \phi$. That is, the sinusoidal iPRC will rapidly cause two phase models to synchronize when subjected to identical noise. (See below for the more general setting.)

The phase reduction also allows us to compute several quantities related to neural coding that are generally difficult or impossible to calculate explicitly. The *spike-triggered average* (STA) is the average value of a stimulus to a neuron conditioned on the spike time. That is,

Phase Models, Noisy, Fig. 1 (Left) Stochastic synchronization of two HH neurons subjected to identical noise (inset shows iPRC). (Right) Synchronization of the phase model

$$\text{STA}(t) = \langle I(t_{sp} - t) \rangle_{\text{spike times}}$$

The STA tells you what aspects of the stimulus that neuron is interested in. Another quantity that gives insight into the “features” of the stimulus that cause spiking is the *spike-triggered covariance* (STC):

$$\text{STC}(t_1, t_2) = \langle I(t_{sp} - t_1) \rangle_{\text{spike times}} - \text{STA}(t_1)\text{STA}(t_2)$$

With weak white noise, both of these quantities can be computed for the noisy phase model (Ermentrout et al. 2007b; Arthur et al. 2012; Ota et al. 2012).

$$\begin{aligned} \text{STA}(t) &= -\varepsilon^2 \Delta'(T - t) \\ \text{STC}(t_1, t_2) &= \varepsilon^2 \delta(t_2 - t_1) + \varepsilon^4 \Delta''(T - t_2) \Delta(T - t_1) H_0(t_2 - t_1) \\ &\quad + \varepsilon^4 \Delta''(T - t_1) \Delta(T - t_2) H_0(t_1 - t_2) \end{aligned}$$

where $H_0(t)$ is the step function with $H_0(0) = 1/2$. The first term in the covariance arises from the autocorrelation of the stimulus. The formula for the STA can be used to estimate the iPRC as it is reasonably easy to experimentally estimate the STA. To estimate the iPRC from the STA, one needs only to integrate the STA and change the sign. Since integration is a “smoothing” operation, the STA method is an excellent way to estimate the iPRC (Burton et al. 2012). A review of

methods for estimating the iPRC is given in Torben-Nielsen et al. (2010).

Noise and Coupling

It is well known that coupling of oscillators via synapses or through gap junctions can lead to *phase-locking*; that is, the two oscillators will spike with a characteristic timing difference. Two commonly observed patterns are synchrony and *anti-phase* where they fire at exactly one half a cycle apart. In the case of synchrony, the distribution of phase differences is a delta function centered at 0. However, if the oscillators are subject to *independent* noise, we can expect that the phase difference will not be identically zero, but rather, there will be some drift. Let us consider coupling that is weak enough so that the phase reduction is valid and noise that is also weak. For simplicity of exposition, suppose the synapses are not time dependent, but, instead, just functions of the phase (voltage). Then, the two coupled phase models are

$$\begin{aligned} \theta'_1 &= 1 + \varepsilon S(\theta_2) \Delta(\theta_1) + \sqrt{\varepsilon} \xi_1(t) \Delta(\theta_1) \\ \theta'_2 &= 1 + \varepsilon S(\theta_1) \Delta(\theta_2) + \sqrt{\varepsilon} \xi_2(t) \Delta(\theta_2). \end{aligned} \quad (6)$$

The oscillators are identical and the noise is white. Here $S(\theta)$ is the pulse coupling. The phase density is found to be

$$P(\phi) = N \exp \left(- \left(\frac{1}{\sqrt{2D}} \right) \int_0^\phi g(s) ds \right)$$

where D is the diffusion coefficient calculated above, N is a normalization so that the integral of P is 1, and

$$g(\phi) = \int_0^{2\pi} [S(t + \phi) \Delta(t) - S, (t), \Delta, (t - \phi)] dt.$$

The function $g(\phi)$ is the coupling function between the two oscillators (see entry ► “[Weak Coupling Theory](#)”). Values of ϕ where g vanishes represent phase-locked states and if $g'(\phi) < 0$, then it is a stable phase-locked state. The phase-difference density, $P(\phi)$, will have local maxima at stable locked states and local minima at unstable locked states. Thus, the phase differences will most (least) likely be found in the vicinity of phases that represent stable (unstable) locked states of the noise-free model. Figure 2 shows an example with a delta function synapse and a sinusoidal iPRC. The simulations and formula for the density agree very well.

Stochastic Synchronization

When two dynamical systems receive identical noise, then if the noise is not too strong, they will often synchronize (Pikovsky et al. 2003;

Phase Models, Noisy, Fig. 2 Effect of noise on coupling $\Delta(\theta) = -\sin \theta$, $S(\theta) = \delta(\theta)$, $\epsilon = 0.1$ theory and simulation are shown

Teramae and Tanaka 2004; Ermentrout et al. 2007a; Nakao et al. 2007; Arai and Nakao 2008). Figure 1 illustrates this phenomenon with the Hodgkin-Huxley model. The two oscillators (both the full spiking model and the phase-reduced system) converge to the same trajectory even though they started far out of phase. This phenomena is called *stochastic synchronization* and the rate of convergence to synchrony is determined by the Lyapunov exponent that was computed above for the phase model. In real biological systems, there is always extraneous noise so that there will never be perfect synchrony. Furthermore, no two neurons are the same so there will also be heterogeneities. Thus, we would like to characterize the degree of synchrony, that is, the phase density, for two oscillators receiving partially correlated noise. If the noise is small, then $P(\phi)$ can be calculated in a wide range of situations such as with colored noise, differently shaped iPRCs, and different natural frequencies (Burton et al. 2012). For simplicity of exposition, we consider only the case where the noise is white and partially correlated (Marella and Ermentrout 2008). The equations are similar to Eq. 6, but, rather than coupling, there is correlated noise:

$$\begin{aligned} \theta'_1 &= 1 + \epsilon \xi_1(t) \Delta(\theta_1) \\ \theta'_2 &= 1 + \epsilon \xi_2(t) \Delta(\theta_2). \end{aligned} \quad (7)$$

To introduce correlation, $\xi_i(t) = \sqrt{c} \zeta(t) + \sqrt{1-c} \zeta_i(t)$ where c is the correlation and $\zeta_{1,2}$ are independent. Thus, when $c = 0$, the two phase oscillators are driven with independent noise and when $c = 1$, they receive identical noise. Marella and Ermentrout (2008) computed the phase density for identical oscillators receiving white noise:

$$\begin{aligned} P(\phi) &= \frac{N}{1 - c \frac{h(\phi)}{h(0)}}, \text{ where} \\ h(\phi) &= \int_0^{2\pi} \Delta(s) \Delta(s + \phi) ds \end{aligned} \quad (8)$$

N is a normalization so that $P(\phi)$ integrates to 1. The function $h(\phi)$ is an even function of ϕ as can be seen from its definition and $h(0) \geq h(\phi)$.

Note also that $h(0)$ is proportional to the diffusion constant in Eq. 4 (for $\tau \rightarrow 0$, the white noise case). Thus, we can see that the bigger the difference between $h(0)$ and $h(\phi)$, the sharper will be the phase density. To lowest order in the magnitude of the noise, $P(\phi)$ is independent of the noise magnitude; intuitively, while strong common noise will push the oscillators together, the strong independent noise will push them apart.

Figure 3 shows the results of simulations and theory applied to the oscillator with $\Delta(\theta) = \sin(a) - \sin(a + \theta)$ where a is a parameter. Clearly, when $a = 0$, the peak is sharpest and synchronization is much better than when $a = \pi/2$. In general, the larger the DC component in the iPRC, the broader the peak. This is connected to the Lyapunov exponent, Eq. 5 since a purely DC iPRC (constant iPRC) has zero derivative and will

not cause any synchronization. Only the modulatory part of the iPRC contributes to the synchronization, but the DC part contributes only to the diffusion, so the optimum way to synchronize through common inputs is to reduce the DC component relative to the modulatory components (Abouzeid and Ermentrout 2009). The formula for $P(\phi)$ is not particularly transparent; however, $P(0)$ is the peak of the cross-correlation function, so the larger this is, the tighter the synchrony. For small values of c , the following formula holds:

$$P(0) = \frac{c}{2\pi} \left(1 - \frac{\langle \Delta \rangle^2}{D} \right)$$

where $\langle \Delta \rangle$ is the average of the iPRC and D is the diffusion coefficient defined above. Thus, if the iPRC is such that the regions where the phase

Phase Models, Noisy,

Fig. 3 The phase density for two oscillators receiving noise with correlation 0.8. *Top*, simulations with three different iPRCs; *Bottom*, theory from Eq. 8

is advanced exactly balance where it is delayed (e.g., $\Delta(\theta) = -\sin \theta$), then $P(0)$ will be maximal.

In sum, the reduction of noisy isolated and/or coupled oscillators to phase models allows one to compute many aspects of their dynamics. As expected, independent noise fights against synchrony for coupled oscillators; in contrast, correlated noise can induce synchrony even when the oscillators are not connected.

Phase Response Curve, Measurement and Shape of General

Theoden I. Netoff

Department of Biomedical Engineering,
University of Minnesota, Minneapolis, MN, USA

Definition

The phase response curve (PRC) is a measure of how an arbitrary stimulus affects the timing of action potentials in a periodically firing neuron depending upon the phase of the oscillation when the stimulus is applied. The shape of this function can determine a lot about how a network of neurons will synchronize when coupled (see entries on ► [“Weak Coupling Theory”](#) and ► [“Pulse-Coupled Oscillators”](#)). The shape of a neuron’s PRC is determined by its intrinsic dynamics, as well as by the shape of the stimulus that is applied. Any change in the shape of the PRC may affect how networks synchronize or how quickly they synchronize. What influences the shape of the PRC to an arbitrary stimulus?

This section will review how intrinsic factors, such as firing rate, potassium channel and sodium channel kinetics, and causality, as well as extrinsic factors, such as synaptic kinetics, reversal potentials, and delays, affect the shape of the PRC.

Detailed Description

Theoretical Analysis of the PRC Shape

Many neurons, when driven with sufficient current, will fire periodically. The PRC, by definition, is a measure of how a stimulus perturbs the neuron from this period as a function of the phase at which the stimulus is applied. To represent the neuron's activity, we usually measure a state of the neuron, such as the voltage, and plot it against time. An example of a voltage trace taken from a

computational model of a neuron is shown at the top of Fig. 1. However, there are often other states (such as the sodium channel activation and the potassium channel activation), which are important in determining the cell's behavior. These states may or may not be observable. To understand what influences the shape of the PRC, we will start with a brief description of a simple computational model and how to analyze its behavior as a dynamical system. We can then go on to look at how various parameters in the model affect the PRC's shape.

Phase Plane Analysis of $I_{NaP,K}$ Model

To illustrate how the PRC depends on different factors, we will use a phase plane analysis of a simple computational model, the persistent sodium plus potassium, the $I_{NaP,K}$ (Izhikevich

Phase Response Curve, Measurement and Shape of General, Fig. 1 Periodic firing and the limit cycle in phase space. Bifurcation from rest to firing in $I_{NaP,K}$ model neuron as current injected into neuron is changed. Left column shows saddle node bifurcation for model, using n -half activation = -25 mV, while in the right panels, the model goes through a Hopf bifurcation using n -half activation = -39.5 mV. Top row, voltage trace under three conditions: subthreshold (blue), at threshold (green), and superthreshold (red). Middle, n -nullcline plotted in cyan and V -nullcline plotted for three different amounts of injected current (solid blue = $-10 \frac{\mu A}{cm^2}$, green = 4.5 , red = 20) as well as the corresponding state space behavior starting at initial condition $V(0) = -75$, $n(0) = 0.1$ for the different currents in the same color (dotted lines). The major difference in the two bifurcation types is clear from the insets: the green trace shows the voltage nullcline at the bifurcation point. For the saddle node on the left, it is tangent to the cyan n -nullcline, whereas on the right the intersection at the bifurcation point occurs as the slope of the V -nullcline changes direction

2007). This model incorporates a fast voltage-gated sodium channel, a persistent sodium channel, and a potassium channel. While this model is not an accurate model of a mammalian neuron, it is convenient to illustrate the dynamics of a neuron. It is closely related to the Morris-Lecar neuron (Rinzel and Ermentrout 1989).

In the $I_{NaP,K}$ model, two states determine the cell's behavior: the voltage and the potassium channel activation. This means that the state of the neuron can be determined unambiguously at any time by knowing the voltage and the potassium conductance states. The equations determining the behavior of the $I_{NaP,K}$ model are as follows:

$$\frac{dv}{dt} = \frac{1}{C}(I - g_l(V - E_l) - g_{Na}m_\infty(V)(V - E_{Na}) - g_K n(V - E_K))$$

$$\frac{dn}{dt} = (n_\infty - n)/\tau_n$$

$$m_\infty(V) = \frac{1}{1 + e^{\frac{V_m - V}{k_m}}}$$

$$n_\infty(V) = \frac{1}{1 + e^{\frac{V_n - V}{k_n}}}$$

where V is the membrane voltage in millivolts; n is the cellular inactivation, a combination of the sodium inactivation and the potassium current; $C = 1 \frac{\mu F}{cm^2}$, is the membrane capacitance; $g_l = 8 \frac{mS}{cm^2}$ is the maximum leak conductance; $E_l = -80$ mV is the reversal potential of the leak current; $g_{Na} = 20 \frac{mS}{cm^2}$ is the maximum sodium conductance; $E_{Na} = 60$ mV is the sodium reversal potential; $g_K = 10 \frac{mS}{cm^2}$ is the maximum potassium conductance; $E_K = -90$ mV is the potassium reversal potential; $V_m = -20$ mV is potential at which half of the sodium channels are open; $k_m = 15$ mV is the slope at half activation; $V_n = -25$ mV is the half activation potassium channel; and $k_n = 5$ is the slope at half activation.

In analyzing dynamical systems, it is helpful to plot the nullclines in state space. The nullclines are the functions in state space along which the derivative of one of the states is zero. The voltage nullcline (plotted in blue in middle panel of Fig. 2)

is determined by setting $\frac{dV}{dt} = 0$ and then solving for n in terms of V :

$$n_{V_0} = (I - g_l(V - E_l) - g_{Na}m_\infty(V)(V - E_{Na})) / (g_K(V - E_K))$$

Likewise, the inactivation state n -nullcline (plotted in green in middle panel of Fig. 2) is determined by setting the $\frac{dn}{dt} = 0$ and again solving for n in terms of V :

$$n_{n_0} = n_\infty$$

Crossing points of the nullclines, where the derivatives in both the V and n directions are zero, are called fixed points. Some fixed points are *stably attracting*, meaning if the neuron's state is perturbed from the fixed point, it will return to the fixed point, while others are *unstable* fixed points, where the neuron's state will accelerate away from the fixed point after perturbation. At low currents there exists a stable fixed point and neuron will sit at rest. As current is injected into the neuron, the V -nullcline shifts upward. At some current value, the intersection goes away or becomes unstable, and the neuron begins to fire periodically. This is an example of a *bifurcation*, which is a qualitative change in the dynamics of a dynamical system that is produced by varying parameters. More detail is given in the entry on ► “Excitability: Types I, II, and III.” In the $I_{NaP,K}$ model, the stable fixed point can become unstable through a bifurcation in one of the two ways: in the first, the V -nullcline initially intersects the other nullcline in three points, but as depolarizing current is added to the model, the nullcline shifts up until two of the intersections are lost simultaneously. At the point of the bifurcation, the voltage nullcline (green trace in the left middle panel of Fig. 1) becomes tangent to the n -nullcline; the two crossing points merge into a single point that is stable in some directions and unstable in others; this is called a *saddle node*. The bifurcation is called a *saddle node bifurcation* as shown in the left column of Fig. 1; trajectories that pass near this saddle node can be arbitrarily slow. In the other bifurcation, the angle of the lone intersection

Phase Response Curve, Measurement and Shape of General, Fig. 2 Types I and II PRCs. The left column represents the dynamics of the $I_{NaP,K}$ model when the half activation of the n -channel is at -25 mV and input current is 5, while in the right column the half activation is at -39.5 mV and input current is 10. Top: voltage traces

from the $I_{NaP,K}$ model. Middle: nullclines determine phase advance. The type of PRC depends on the bifurcation of the neuron from rest to spiking. **Bottom:** Type I PRCs only have phase advances given a small excitatory input, whereas Type II PRCs can have both advances and delays

P

between the two nullclines changes until the stable fixed point becomes unstable, resulting in repetitive spiking with onset at a nonzero threshold frequency. This is called a *Hopf bifurcation* and is shown in the right column of Fig. 1. The difference between the model in the left and right condition is the half activation voltage of the n -state (cyan curve). In the left column, the half activation is at -25 mV, and in the right column, it is at -39.5 mV.

When a neuron is firing periodically and the voltage is plotted against the potassium activation, the trace forms an orbit. If the orbit is a stable behavior, meaning that if the neuron's state is perturbed off the orbit by a small amount, it will return to the orbit, it is called a limit cycle. The orbit for a periodically firing $I_{NaP,K}$ neuron is

shown in the middle panel of Fig. 3. The phase of the oscillation can be thought of as the angle of a hand on a clock, where the hand starts at some point in the center of the orbit (such as the unstable fixed point in the center of the orbit) and the tip of the hand points to the current state of the cell. If the voltage and the inactivation are thought of as a Cartesian coordinate representation of the neuron's state, the phase angle is a polar representation.

When a neuron is stimulated by an external input, such as a synaptic input or an injected current from an electrode, it pushes the neuron's state off its orbit. Because the orbit is stable, the neuron's state will return back to the orbit. However, when it returns to the orbit, the phase may be advanced or delayed. The degree to which the

Phase Response Curve, Measurement and Shape of General, Fig. 3 Top, voltage plotted against time of a periodically firing $I_{NaP,K}$ model neuron. At time 8.5, a stimulus is applied which instantaneously increases the voltage by 4 mV. The *red trace* indicates the voltage trace after the stimulus is applied. Middle, voltage (V) plotted against cellular inactivation (n). The periodically firing neuron follows an orbit in this state space representation. The *blue dots* represent the states sampled at each 0.1 ms. The higher density along the orbit indicates slower moving state. The *black lines* are isochrons, sampled at every 0.5 ms. They represent points in state space along which initial conditions will result in all points on the line converging to the same phase on the limit cycle. The *blue triangle* represents the phase of the neuron before the stimulus and the *red triangle* represents the phase immediately after. The voltage and inactivation follow the *red curve* after the stimulus and converge back onto the stable limit cycle. 3 ms after the stimulus is applied, the unperturbed and perturbed states are plotted as *blue and red circles*. The stimulus has moved the neuron across isochrons advancing the phase of the neuron. Bottom, by repeatedly stimulating the neuron at different phases, the time difference between the unperturbed condition and the stimulated condition is the phase response curve

phase is shifted depends on the phase of the neuron's cycle at the time of stimulus, the shape of the stimulus pulse, and the dynamics of the neuron that determine how the state returns to the orbit.

The phase response curve can be directly determined by plotting the relationship between the cycle period and the phase of the cycle at which the stimulus was applied. The cycle period is determined by choosing a point along the orbit and measuring the time it takes to complete a cycle and return to the same point. This time will vary to different degrees when the stimulus is applied at different phases of the cycle. The PRC for the $I_{NaP,K}$ model is shown at the bottom of Fig. 3.

Type I and Type II PRCs

If the phase response curve is strictly positive, i.e., a weak excitatory input only can advance the spike time, it is called a Type I or Class I PRC (Rinzel and Ermentrout 1989). The $I_{NaP,K}$ model can produce both Type I (left column) and Type II (right column) PRCs, as shown in Fig. 2. These types are closely tied to two classes of cell excitability that Hodgkin described as Type I and Type II neurons (Hodgkin 1948). Hodgkin characterized Type I cells as those that have sharp thresholds and can fire at very slow firing rates. As the $I_{NaP,K}$ model goes through a saddle node bifurcation, it has a sharp threshold and can fire at arbitrary low firing rates, and for excitatory inputs, the phase response curve only contains advances of the next spike. Alternatively, if a stimulation can both advance and delay the next spike with an excitatory input, the PRC is called Class II or Type II. An example of the $I_{NaP,K}$ neuron model with parameters to generate Type II behavior occurs when a neuron is very close to a Hopf bifurcation.

Measuring the Phase Response Curve

The phase response curve to an arbitrary stimulus wave form can be measured by the direct method: a stimulus is applied to the neuron, and the change in spike time from the unperturbed interspike interval is measured. In Figs. 3 and 4, a stimulus is simulated by instantaneously adding 2 mV to the neuron's voltage. This simulates a very strong but very short pulse. In Figs. 5, 6, 7, 8, 9, and 10, a more realistic stimulus is applied to simulate synaptic input to the cell:

$$g_{\text{syn}}(t) = \frac{1}{\tau_s - \tau_f} \left(e^{-\frac{t}{\tau_s}} - e^{-\frac{t}{\tau_f}} \right)$$

where τ_s is the slow decay time constant of the synapse, τ_f is the fast rise time constant, and $\frac{1}{\tau_s - \tau_f}$ is a normalization factor so that the total area under the curve is 1 independent of the shape of

the synaptic conductance. In these simulations, because the $I_{\text{NaP,K}}$ neuron has such a short period (about 7 ms), we used a fast synapse with short time constants $\tau_s = 0.5$ ms and $\tau_f = 0.25$ ms.

When adding the synapse to the model, the voltage equation becomes

$$\frac{dv}{dt} = \frac{1}{C} \left(I - g_I(V - E_I) - g_{\text{Na}} h_{\infty}(V) (V - E_{\text{Na}}) - g_K n(V - E_K) - g_{\text{syn}}(t) (V - E_{\text{syn}}) \right)$$

The synaptic waveform can be written as a differential equation:

$$g_{\text{syn}}(t) = \frac{g_{\text{syn}}^{\text{max}}}{\tau_s - \tau_f} (s - f)$$

where

$$\frac{ds}{dt} = -s/\tau_s$$

$$\frac{df}{dt} = -f/\tau_f$$

Phase Response Curve, Measurement and Shape of General, Fig. 4 Effect of firing rate on the shape of PRC measured with voltage perturbation. As more current I is applied to the neuron, the firing rate increases and the interspike interval (ISI) decreases. At higher firing rates, neurons become dominated by their own internal dynamics and become less sensitive to external perturbations

The variable s represents the slow component of the synapse and f is the fast component. To simulate a synaptic input, 1 is added to both the s and f variables at the time of the input, and the states s and f are integrated along with the V and n states. The coefficient $g_{\text{syn}}^{\text{max}}$ scales the synaptic amplitude. What are s and f ?

To measure the PRC in a model, a simulation is run from the start of an action potential, for example, the upward crossing at -20 mV, to the onset of the stimulus time, the stimulus is applied, and then the numerical simulations are continued until the voltage crosses the threshold again. The PRC is determined by plotting the difference between the measured interspike intervals (ISI) given the stimulus at phase ϕ , $\text{ISI}(\phi)$, from the unperturbed ISI:

$$\Delta(\phi) = (\text{ISI}_{\text{un}} - \text{ISI}(\phi)) / \text{ISI}_{\text{un}}$$

The direct method can be used to detect the effect of changes in the shape of the stimulus as well as the effect on changes in the dynamics of the neuron. For sufficiently weak coupling, the results of the direct method agree with that predicted by convolving the PRC in response to an infinitesimally brief and weak input (see entry on ▶ “Weak Coupling Theory”) with the shape of the arbitrary perturbation.

Isochrons

When a neuron is perturbed off the orbit, it may return to the orbit either ahead or behind the phase of its unperturbed orbit. There are lines in state

Phase Response Curve, Measurement and Shape of General, Fig. 5 Effect of changing fast voltage-gated sodium channel conductance on the shape of the PRC. PRC measured with synaptic input waveform ($I = 10 \frac{\mu\text{A}}{\text{cm}^2}$ for all simulations, $g_{Na} = 20 \frac{\text{mS}}{\text{cm}^2}$ in all other simulations shown). Increasing the fast voltage-gated sodium

conductance makes the model less sensitive to inputs that occur after the neuron recovers from the action potential. This may be partially be attributed to the increased firing rate. The right panel shows that as g_{Na} increases, the interspike interval decreases

Phase Response Curve, Measurement and Shape of General, Fig. 6 Effect of voltage-gated potassium channel conductance on the shape of the PRC. Default potassium conductance is $10 \frac{\text{mS}}{\text{cm}^2}$. As potassium conductance g_K

is increased, the $I_{NaP,K}$ model becomes more sensitive to synaptic inputs. The red dotted line is the causality line, as discussed below

space where if the state of the neuron is placed at any point along the line, the neuron will converge to the same phase of the orbit. These lines are called *isochrons* (Greek *iso*, same; *chronos*, time). The isochrons for the $I_{NaP,K}$ model are shown in Fig. 3. To find these isochrons in a computational model, we use a trick: an attracting point in state space when integrating the model forward in time becomes a repelling point when integrating the model backward in time.

Therefore, we choose initial conditions very close to the orbit and then integrate them backward in time. As the points diverge, new points can be inserted or, if the points get too far away from the limit cycle, eliminated. The resulting isochrons plotted at 1 ms intervals starting at the threshold at -20 mV are plotted in the middle panel of Fig. 3.

When a stimulus moves the state of the neuron across these isochrons, it causes a phase advance.

Phase Response Curve, Measurement and Shape of General,

Fig. 7 Response to synaptic amplitude limited by causality. Stimuli cannot advance the action potential to a time prior to the onset of the stimulus. The line of causality is plotted as a red dashed line $C(\phi) = 1 - \phi$. It is impossible to advance a spike above this line. As an excitatory stimulus amplitude is increased, the shape of the PRC is affected by the line of causality, forcing the peak to the left

Phase Response Curve, Measurement and Shape of General, Fig. 8 Effect of the synaptic time constant on the PRC. As the falling time constant of the synapse is increased (synaptic waveforms are plotted in inset), when preserving total charge, the amplitude becomes smaller and

the peak shifts slightly to the right. Faster synapses tend to elicit larger PRCs than slower ones. Slowing of the synapse smooths over the cell dynamics, making the PRC flatter. Slowing of the synapse also acts like a time delay, moving the PRC forward in phase

The phase advance may not be realized until the neuron has relaxed back to its orbit. An example of a 2 mV stimulus moving the state across the isochrons is shown in Fig. 3. When the state is plotted 3 ms later, and compared to the unperturbed state at the same time, it can be seen that the stimulus resulted in a phase advance. The

shape of the phase response curve is therefore directly related to how the stimulus causes the neuron to cut across these isochrons.

If the isochrons are dense near the phase at which the stimulus is applied, the phase advance will be larger than it would be if the stimulus was applied at a phase where the isochrons are widely

Phase Response Curve, Measurement and Shape of General, Fig. 9 Effect of synaptic reversal potential on PRC. Excitatory and inhibitory synaptic inputs differ by their kinetics and by the synaptic reversal potential. In this plot, the kinetics are held constant as the reversal potential is changed. Because of the nonlinearities of the neuron, and the different effects of causality on spike advance versus spike delays, excitatory and inhibitory inputs are not symmetric around the resting potential, i.e., if the neuron at rest

is at -60 mV and if the neuron's response is linear, then a synaptic input with a reversal potential of -80 mV should have the same shape but with a sign reversal as a synaptic input with a reversal potential at -40 mV. It can be seen that the blue and red lines are not the same, indicating that there are nonlinearities in the response. Generally, PRCs for inhibitory synaptic inputs usually peak at the very end of the phase, while excitatory inputs tend to peak earlier

Phase Response Curve, Measurement and Shape of General, Fig. 10 Effect of synaptic delay on phase response curve, second-order PRC, and total PRC response. As synaptic inputs are delayed, the PRC shifts to the left (*solid line*). Secondary PRCs measure the effect of spike advance on the interspike interval following the

stimulus period (*dashed line*). As synaptic inputs are delayed, more of the current is applied on the subsequent interval, resulting in significant phase advances on the second period. The second-order PRC and the primary PRCs can be added together to estimate the total effect of the synapse on the spike times (*dotted lines*)

spaced. However, the degree of phase advance also depends on the direction of the stimulus with respect to the isochrons. If the stimulus moves the states orthogonal to the isochrons, the phase advance will be maximal for a given stimulus amplitude. If the stimulus moves the state along isochrons, the phase advance will be minimal. In the middle panel of Fig. 3, the stimulus increases the voltage (i.e., moves it to the right). When the stimulus is applied at the phase indicated by **A**, it moves the state along the isochrons, resulting in a small change of phase. A stimulus applied at the phase indicated by **B** moves the state across isochrons, resulting in a large change.

The shape of the PRC is also dependent on how long the neuron dwells in states sensitive to inputs and in states that are not sensitive to inputs. In the neuron model, the phase does not progress linearly with time. Dots are plotted along the orbit at 0.1 ms intervals. It can be seen from the density of dots that the neuron spends more times at phases during the recovery period, where there is a high density of dots, than at the action potential, where the density is low. Because the neuron spends a good portion of the time in the recovery phase where the cell is insensitive to voltage perturbations, the PRC is flat for a good portion of the phase. As the neuron approaches threshold again, it becomes sensitive again to inputs.

The remaining sections will detail how changes in the dynamics of the cell and the synapse affect the measured PRC. The first part will focus on changes intrinsic to the neuron, such as changes in the kinetics of voltage-gated ion channels which may be caused by drugs or ion channel mutations. The second part will focus on changes extrinsic to the neuron, such as changes to the shape of the synapse.

Intrinsic Effects on PRC Shape

Firing Rate of the Neuron

As the current applied to a neuron increases, the firing rate generally increases. This in turn affects the neuron's sensitivity to synaptic inputs. As its sensitivity changes to inputs, the ability of the network to synchronize may

change. Changes in PRC shape as a function of firing rate can be used to explain how networks of neurons synchronize at certain firing rates and desynchronize at others.

Tonic excitatory synaptic drive depolarizes a neuron and increases its firing rate. As the firing rate increases, the period shortens, but the action potential and the recovery time do not. Therefore, the proportion of the PRC dedicated to the action potential and recovery time increases. In this model there is a small phase delay when a stimulus is applied during the action potential (at the beginning of the phase), as can be seen as a small dip in the PRC in Fig. 4. As the ISI shortens as the applied current is increased, the action potential width does not change; therefore this phase at which the action potential ends moves to the right, as can be seen with the rightward movement of the dip. This illustrates that the proportion of the PRC affected by the action potential increases as the ISI decreases.

It can also be seen in Fig. 4 that at the slow firing rate, when the input current $I = 5 \frac{\mu A}{cm^2}$, the phase response curve is quite large, but at the high firing rate, when the input current $I = 15 \frac{\mu A}{cm^2}$, the peak of the PRC decreases. This is because when a neuron is driven to fire very rapidly, its dynamics are dominated by its internal dynamics, which are determined by gating of the ion channels; therefore, if the cell receives a synaptic input when it is firing rapidly, its phase will not change dramatically. At smaller currents the firing rate of the neuron slows, and the neuron becomes more sensitive to external inputs.

Ion Channel Kinetics

There are many parameters associated with the voltage-gated sodium and potassium currents: maximum conductance, half activation voltage, slope at half activation, and the time constants. The kinetics of these channels can be affected by different drugs and by genetic mutations. PRCs are a powerful tool to relate these changes at the molecular level to changes in network behavior.

In Fig. 5 PRCs from the $I_{NaP,K}$ model are shown as the maximum sodium conductance is changed. Increasing the sodium conductance decreases the peak of the PRC. This may be due

to the fact that sodium conductance and firing rate are negatively correlated, as shown in the right panel of Fig. 5. Because increases in sodium conductance result in higher firing rates and shorter ISIs, the neuron becomes less sensitive to synaptic inputs. The peak of the PRC also shifts to the right with increased sodium conductance. That may be attributed to effects from the line of causality, addressed later.

In Fig. 4 the PRC was measured using an instantaneous change in voltage, while in Fig. 5 it is measured with a realistic synaptic input. The PRC shape looks different due to the synaptic dynamics. The blue curve in Fig. 5 corresponding to $g_{\text{Na}} = 20 \frac{\text{mS}}{\text{cm}^2}$ with synaptic input can be compared directly to the red curve in Fig. 4 corresponding to $I = 10 \frac{\mu\text{A}}{\text{cm}^2}$ with a voltage change. Because the synaptic input is applied over a finite time, it smooths and advances the PRC to the left.

The voltage-gated potassium current is important in the recovery of the neuron from an action potential and restoring the cell to rest. It can be seen in Fig. 6 that as the voltage-gated potassium current is increased from 6 to $14 \frac{\text{mS}}{\text{cm}^2}$ (default is $10 \frac{\text{mS}}{\text{cm}^2}$), the cell becomes more sensitive to synaptic inputs and for a longer portion of the phase. Like the sodium conductance, increasing potassium conductance decreases the ISI. In contrast to the sodium conductance, increasing the potassium conductance makes the cell more sensitive to synaptic inputs. The increased potassium current helps the cell recover from the action potential faster letting the cell spend more of its phase near threshold where it is sensitive to inputs.

Causality

When a stimulus is applied, the maximum amount that it can advance the spike is to immediately elicit an action potential. The stimulus cannot make the neuron fire an action potential prior to the time the stimulus is applied. This is called *causality*. The causality line can be plotted on the PRC graph, $C(\phi) = 1 - \phi$, shown as dashed red lines in Figs. 6 and 7. It is zero when $\phi = 1$ and increases at a 45° angle backward from the end of the phase (note that the figure does not have the same scale for the x and y direction). Instantaneous activation

of an action potential would result in points along this line. Because a stimulus cannot advance an action potential to a time prior to the onset of the stimulus, it is not possible for points to exist above this causality line.

For very small stimulus amplitudes, as the amplitude is increased, the PRC will increase proportionally. However, as the stimulus amplitude becomes larger, the stimulus transitions from modulating the spike times to eliciting spikes. This can be seen when the PRC begins to hug the line of causality. As seen in Fig. 7, as the stimulus amplitude increases, the peak of the PRC is forced to the left by the causality limit. The PRC cannot actually be on the line of causality because the synaptic waveform is finite, and there will always be a time lag between the onset of the stimulus and the threshold crossing of the action potential. This lag will result in a PRC that is slightly below the line of causality, even for the largest stimulus. Plotting the PRC with the line of causality is a good tool to assess whether the stimulus is inducing linear or nonlinear responses. If a large number of points are sitting along the line of causality, it implies that the stimulus is evoking an action potential rather than phase advancing and the response is therefore nonlinear.

For inhibitory inputs, increasing the amplitude can delay the spike almost indefinitely. Therefore, for large stimulus amplitudes, changing the sign of the stimulus, even without changing any other parameters, may result in asymmetries in the PRCs due to the different effects of causality on delaying versus advancing stimuli. This is one of the reasons why an excitatory and an inhibitory synaptic input may elicit PRCs which are not symmetrical.

Extrinsic Effects on PRC Shape

Synaptic Time Constants

The shape of a synaptic conductance waveform is dependent on the neurotransmitter release, the clearing of the neurotransmitter from the synapse, and the receptor density and kinetics. The synaptic release and receptor kinetics can change on the short time scales caused by short-term potentiation and facilitation, as well as by neuromodulators and

drugs. Changes in receptor density can be affected by long-term potentiation or homeostatic plasticity. All of these changes can alter the way networks of neurons synchronize on fast time scales, such as with the waxing and waning of population oscillations, or over slow time scales, such as with the development of pathological behaviors. The PRC is also affected by the synaptic reversal potential, which can change with the accumulation of ions in the extracellular and intracellular space.

As the rates of neurotransmitter uptake and enzymatic breakdown are changed, the time constants of the synaptic waveform are affected. Here we use an alpha function to simulate the synaptic conductance waveform:

$$g_{\text{syn}}(t) = \frac{1}{\tau_s - \tau_f} \left(e^{-\frac{t}{\tau_s}} - e^{-\frac{t}{\tau_f}} \right)$$

In Fig. 8 we vary the time constant of the synaptic decay. As the decay time is increased, the synapse smooths over a larger portion of the cell's phase. To normalize the stimulus waveforms, the total charge passed is held constant as the time constants are changed. Therefore, the peak synaptic amplitude is greater for synapses with faster kinetics. Because neurons are more sensitive to fast inputs, faster synapses tend to elicit taller PRCs than slower ones, given the same total charge. The slowing of the synapse also acts like a time delay by shifting the peak of the PRC to the left. The effect of time delay will be addressed in a later section.

Synaptic Reversal Potential

The synaptic current is a function of the synaptic conductance waveform and the synaptic reversal potential. $I_{\text{syn}} = g(\text{syn})(E_{\text{syn}} - V_m)$. In Fig. 9 the synaptic conductance waveform is held constant, but the synaptic reversal potential is varied from an inhibitory synaptic reversal potential of -80 mV to an excitatory synaptic reversal potential of 0 mV. If the neuron's response was strictly linear, applying a synaptic input with a reversal potential 20 mV above rest and one 20 mV below rest would result in the same PRCs but with a sign reversal. However, it can be seen that these PRCs are not, indicating that the response is nonlinear. One obvious difference between PRCs measured

with inhibitory and excitatory synaptic inputs is that spike delays are less affected by causality limits than advances. This results in inhibitory PRCs being more skewed to the right than excitatory PRCs, which skew more to the left as stimulus amplitude increases. But the neuron's dynamics are also nonlinear; this can be seen in Fig. 3 by the fact that the isochrons do not have left-right symmetry around the orbit. Therefore, any finite stimulation that perturbs the neuron significantly off the orbit does not elicit a symmetric effect when pushing the state of the neuron to the right compared to that of a stimulus pushing it to the left of the orbit.

Synaptic Delay

There can be a significant lag, on the order of milliseconds, between the presynaptic action potential and the EPSP observed postsynaptically. As cells get further apart, the propagation time from the soma of the presynaptic cell to the synaptic release site can become significant. For synaptic inputs that occur at distal points on the dendrite, propagation time from the synapse to the soma of the postsynaptic cell can also become significant. Furthermore, the EPSPs from synaptic inputs on distal dendrites can become more smeared out over time as the electrical impulse travels down the dendrite, which effectively acts as a further delay. These synaptic delays can affect the shape of the PRC and have a significant role in determining how a network will synchronize (Crook et al. 1998; Woodman and Canavier 2011; Canavier et al. 2013). Drugs that affect potassium channels can dramatically change the way synaptic inputs propagate along the dendrite, significantly changing the effective synaptic delay times.

PRCs measured with different synaptic delays are plotted in Fig. 10. It can be seen that as the delay gets longer, the PRC shifts forward in phase. For example, if a stimulus is applied at 0.7 of the phase with a delay of 0.1 , it will look the same as a stimulus applied at 9.8 of the phase with a delay. The PRC is shifted forward proportional to the delay. The most significant effect is that the stimulus may not arrive until after the neuron has spiked. In this case, the effect of the stimulus may be observed on the subsequent period. This can be observed in the *higher order PRCs*, described next.

Higher Order PRCs

If a stimulus is finite in duration and the neuron's response takes some time to return back to its orbit, the effect of the stimulus may not be completely resolved by the time the first action potential occurs. Therefore, the effect may be observed on the timing of the second spike after the onset of the stimulus. The measurement of the effect of the stimulus on the interspike interval during which the stimulus was initiated is called the *primary PRC*; the measurement of the effect on the subsequent ISI is called the *secondary PRC*. In general, the effect of the stimulus on any interval following the interval during which the stimulus is initiated is called a *higher order PRC*. Analyzing the primary PRC's effect on network synchrony may lead to erroneous results if higher order effects on subsequent intervals are ignored. The higher order PRCs can be added to the primary PRC to assess the total effect of stimulus on the neurons.

Second-order PRCs are plotted in Fig. 10 as dashed lines. It can be seen that as the synaptic delay is increased, the secondary PRC becomes significantly larger. This is because synaptic inputs initiated at the end of the period may be applied to the next period resulting in significant phase advance of the second action potential. In the case of the $I_{NaP,K}$ neuron, the secondary PRC is flat for the majority of the period except at the very end of the period, where the synaptic input from the previous cycle leaks into the second period. The flatness of the secondary PRC in the early phases indicates that the neuron has recovered from the synaptic input applied early in the first period by the time the second period starts. If the cell's dynamics are slow to recover, the secondary PRC can be significant. In theory, because a PRC is a measurement of the effect of a stimulus on the orbit of a neuron in state space, the PRC itself should be periodic with the phase. However, often it can be seen that for the primary PRC, the phase advance that occurs as a result of stimulation at the beginning of the phase does not match the phase advance due to stimulation at the end of the phase. This indicates that there is a significant effect in the higher order PRC.

The total PRC is the cumulative effects of the first- and second-order PRCs. It can be measured

by calculating the phase advance of the second (or later) spike after the stimulus is applied. The total PRC is plotted as a dotted line in Fig. 10. While the primary and secondary PRC are not periodic (the beginning and the end of the phase do not match), the total PRC is periodic.

Conclusions

Changes in the shape of a PRC may help to determine how network dynamics are altered as a function of cellular level changes. Because neuronal dynamics are highly nonlinear, there are no hard and fast rules that relate changes in ion channel conductance to changes in phase response curves. Therefore, the best approach to understanding these relationships remains performing numerical simulations confirmed with physiological experiments directly measuring the effect of changes in ion channel kinetics on PRC shape.

In general, excitatory inputs will advance spikes, while inhibitory inputs delay spikes. Because of causality, excitatory inputs generally are more skewed to the left. Time delays skew the PRC to the left. Therefore, excitatory inputs with significant delays can result in desynchronization of networks. If the beginning and the end of the phase of the primary PRCs do not match, this is an indication that the stimulus has not been fully applied or the neuron has not returned to the limit cycle by the time the neuron spikes. If this is the case, including higher order PRCs may be necessary to fully characterize the neuron.

Phase Response Curve, Measurement of the Infinitesimal

Klaus Stiefel

The MARCS Institute, University of Western Sydney, Penrith, Australia

Definition

The infinitesimal phase response curve (iPRC) is a measure of an oscillator, which specifies how the phase of that oscillator shifts, as a function of the phase of a perturbation as the width and height of the pulse go to zero, approximating a continuous time delta function (see ► [“Weak Coupling Theory”](#)). In neurons, the iPRC measures the spike time shift in response to the injection of a small

current (or less often a conductance) pulse at a given time. The iPRC should scale linearly with pulse area.

Detailed Description

The iPRC of neurons is of interest for several reasons. First, by using the iPRC, a prediction can be made about the synchronizing properties of synaptically coupled neurons. Given small conduction delays and weak coupling between neurons, nonnegative PRCs (type I PRCs or monophasic PRCs; see ► [“Phase Response Curve, Measurement and Shape of General”](#)) typically lead to synchronization between neurons only if they are coupled via inhibitory connections. In contrast, iPRCs with a negative part (type II PRCs or biphasic PRCs) may lead to synchronization in networks with excitatory coupling (Rinzel and Ermentrout 1998; Hansel et al. 1995).

Secondly, the iPRC type is often indicative of the bifurcation type leading to the transition from non-spiking to spiking state. Moreover, the iPRC type correlates with the excitability type of a neuron (Rinzel and Ermentrout 1998). iPRCs are variable between and within neuronal cell types (pyramidal neurons, Reyes and Fetz 1993; Tsubo et al. 2007; inhibitory interneurons, Tateno and Robinson 2007), across firing frequencies (Gutkin et al. 2005) and neuromodulatory conditions (Stiefel and Gutkin 2012). Determining the iPRC of a neuron hence provides us with significant information regarding its class and functionality.

The high-dimensional dynamics of a neural oscillator can be projected down to a one-dimensional system. In such projection, the state of a neuron as an oscillator is determined by the phase only. The phase monotonically increases at a rate corresponding to the oscillator’s frequency and is reset to 0 every full 2π . When a hypothetical infinitesimally small perturbation (current pulse) is injected into a neuron, then the spike time shifts as a function of the perturbation phase are described by the infinitesimal PRC (iPRC). When a realistic (but still weak and not directly causing a spike) input is injected into a neuron, the PRC is the convolution of the iPRC

with the input waveform (see ► [“Weak Coupling Theory”](#)).

The most straightforward way to determine the iPRC is by injecting brief pulses at random interspike phases into a neuron and plotting the phases against the resulting phase shift. The pulses must be large enough to overcome the effects of background noise, but not so large that they summate nonlinearly. The phase shift is divided by the area under the pulse to get the iPRC in units of phase reset per unit of current (or conductance; see Achuthan et al. 2011). As the observed phase shift data is usually rather noisy, a post-processing step is used to fit a smooth curve to the data (Reyes and Fetz 1993). The intrinsic jitter of the spike times as well as noisiness of observed phase shifts results in the major drawback of this approach: that is, a large number of sweeps with injected perturbations and their resulting phase shifts need to be collected.

An alternative approach is to inject a continuous fluctuating current into the neuron (Izhikevich 2010; Netoff et al. 2005). These current fluctuations will then cause the neuron to emit a spike train. In parallel, a spike train can also be predicted from the fluctuations and a candidate iPRC. The prediction is derived by treating the fluctuations as a series of individual perturbing pulses, and the expected phase shift is their cumulative effect. The iPRC is then determined by optimizing a curve that minimizes the error between the spike times predicted by the candidate iPRC and the observed spike times. The total error is the sum over the square of the differences between these expected phase shifts and the measured phase shifts. The continuous fluctuation can be a convolution of synaptic potential-like waveforms, white or colored noise.

However, the parameters of such an iPRC fitting algorithms do not necessarily converge within a reasonable number of optimization rounds. This is due to the loss of temporal information about the injected fluctuation, which is lost as the error signal is averaged over all phases and all spikes. Optimization methods based on minimizing an error matrix solve this problem (Torben-Nielsen et al. 2010).

A third alternative to the direct and parameter-optimization-based methods is to average the inputs between spikes. Such an average over the inputs over all interspike intervals, integrated and reversed in time, is equivalent to the iPRC (Ermentrout et al. 2007). Scaling the interspike intervals in an additional preprocessing step makes this method more robust against spike timing fluctuations (Ota and Aoyagi 2012).

In conclusion, a number of data analysis methods exist to determine the PRC of a neuron. As in all of time-series analysis, we first need to judge the quality (such as stationarity, noise levels) and quantity of our data. Based on this judgment, we then decide if and how we can determine PRCs. The averaging and parameter-optimization-based methods can potentially outperform the direct method in the face of noise and low spike numbers. These data analysis methods can also be applied to experimental data which was not originally recorded with PRC determination in mind.

Definition

Phase response curves (PRCs) describe how an oscillator responds to input perturbations given at various times during the oscillator cycle. Phase resetting, and by extension PRCs, can be classified as weak or strong based on a geometric analysis of perturbations to the limit cycle (Glass and Winfree 1984). This geometric classification of

PRCs is distinct from that based on the bifurcation structure of the state space (Rinzel and Ermentrout 1989).

Detailed Description

Introduction

Many types of biological systems exhibit oscillations. In neuroscience, oscillations are evident at a variety of spatial and temporal scales, from the repetitive firing of action potentials (single neuron, milliseconds to seconds) to the circadian rhythms evident in the suprachiasmatic nucleus (thousands of neurons, one day).

Computational modeling has evolved since the pioneering work of Hodgkin and Huxley, but for many neural systems, sufficient data may not exist to construct a detailed, conductance-based biophysical model. Nor may it be necessary. A key question for many neural systems is how neurons coordinate the timing of their oscillations (e.g., action potentials) to produce a stable pattern. This question is fundamental for a range of systems, ranging from central pattern-generating circuits to the transient synchrony of neural ensembles in higher-level function (Fell and Axmacher 2011).

Limit Cycle Oscillations and Geometric Phase Resetting

How to answer this question? We first assume that the oscillation is a limit cycle – a trajectory through state space that is repeated reliably every cycle. The phase of a limit cycle, defined over an interval of 0–1 or 0– 2π , describes the current state of the oscillator. A common example of this process is the second hand of a clock. The period of the oscillation (1 min) describes how long it takes for one complete traversal of the limit cycle; the phase is mapped to the location the second hand is currently pointing to.

Assuming a limit cycle oscillation, we make a second assumption – perturbations to the oscillation move the state of an oscillator forward (advance) or backward (delay) along the limit cycle. The phase response curve (PRC) is a function that characterizes how the limit cycle is

advanced or delayed as a function of the phase where the input to the oscillator arrived; there are many variants of this assumption that differ in the details, but they all ultimately assume a characterization of the advance or delay of the oscillation. This formulation has the advantage that it can be experimentally measured (or computationally simulated), assuming the component oscillator can be isolated. An example of the phase response curve and how it is measured is shown in Fig. 1. The time between the oscillator spike and the input perturbation is the stimulus interval t_s ; normalized by the unperturbed period, this becomes the stimulus phase. Phase resetting is defined as the difference between the perturbed oscillator cycle and an unperturbed oscillator cycle,

Phase Response Curve, Topology of,
Fig. 1 Measurement of the phase resetting curve. *Top*, a perturbation arrives at some interval t_s within the interspike interval. This normalized by the unperturbed period P_0 is the stimulus phase. The phase resetting is calculated by normalizing the change in period length of the perturbed interval (in this case $P_1 - P_0$, but it can also be calculated $P_0 - P_1$) by the unperturbed period P_0 . The phase resetting curve or phase response curve is plotted below. (Example is from the model of Wang and Buzsaki 1996)

normalized by the unperturbed period. The amount of phase resetting is dependent on when the oscillator cycle the perturbation is received.

In addition to the phase response curve, information about the phase resetting of an oscillator can be presented on the phase transition curve (PTC), which plots the old phase against the new phase (Glass and Winfree 1984, 1988; Winfree 2000). The old phase is equivalent to the stimulus phase of the PRC, and the new phase is the phase after all perturbation effects are accounted for. The phase transition curve is algebraically related to the PRC, where the new phase is defined as the old phase (stimulus phase) plus the phase resetting.

The winding number of a PTC refers to the number of cycles traversed by the new phase as the old phase traverses one complete cycle from 0 to 1 (Glass and Winfree 1984, 1988). PTCs that increase in new phase from 0 to 1 as old phase is increased from 0 to 1 have a winding number of 1 and are called type I curves; PTCs where new phase does not cover a unit circle (traverse all phases on the circle) when old phase is varied from 0 to 1 have a winding number of 0 and are labeled type 0.

The PTC for a type 1 curve traverses all new phases, but the PTC for a type 0 curve does not. To understand why, we follow the reasoning used in Glass and Winfree (1984) and Glass and Mackey (1988): first assume that a limit cycle encircles an unstable fixed point. Intersecting the limit cycle are lines emanating from the unstable fixed point; these isochron lines demarcate points that have the same phase. For clarity, only eight of the possible oscillator isochrons are shown in Fig. 2, column A. Perturbations push the system off the limit cycle (Fig. 2, column B). A weak perturbation to the oscillator pushes the system off the limit cycle slightly. If weak perturbations are applied at various old phases between 0 and 1, we can redraw the limit cycle as the dotted curve in Fig. 2, column A or as the points in column C.

The strength of the applied perturbations affects how far the limit cycles are shifted; weak perturbations shift the limit cycle, but the unstable fixed point in the center remains enclosed by the limit cycle. In the weak perturbation case, the limit cycle can still progress through all the isochrons it did before the perturbations (Fig. 2, column A);

Phase Response Curve, Topology of, Fig. 2 Examples of weak (*top*) and strong (*bottom*) geometric phase resetting. In the limit cycle schematic (column **A**), the lines represent isochrons, the black trace is the unperturbed limit cycle, and the *dotted curves* represent the shifted limit cycle; the fixed point in the center of the limit cycle is still enclosed by the shifted limit cycle in the weak case but not in the strong case. Column **B** shows the unperturbed (black) and shifted (gray or blue) limit cycle in phase space, represented here as the potassium activation variable n versus membrane voltage V . Shifted limit cycles are calculated by finding n and V of the perturbed limit cycle shortly after perturbation onset. Notice that the weakly shifted limit cycle encloses the fixed point (represented

by a *black diamond*), while the strongly perturbed limit cycle does not. Column **C** illustrates the phase resetting curve in each case, where stimulus phase and phase resetting are defined as in Fig. 1. Column **D** shows the phase transition curve for each case; old phase is equivalent to PRC stimulus phase and new phase is old phase minus the phase resetting (because we have defined our phase reset as $(P1 - P0)/P0$). The model used to generate columns **B** through **D** is the $I_{NaP} + I_K$ model from Izhikevich (2007); parameters are identical to those used in Fig. 4.30 (p. 114). Perturbations to measure the PRC were instantaneous voltage shifts of -10 mV (*top*) and -60 mV (*bottom*)

since the limit cycle can traverse all these phases, the PTC is a continuous function that maps old phases (stimulus phases) to new phases of similar value (Fig. 2, column E). Strong perturbations shift the oscillator limit cycle so far that the unstable fixed point is no longer inside the limit cycle; this makes it impossible for the oscillator to traverse all the phases that were accessible before the strong perturbation. The oscillator new phases are restricted to a subset of the previous old phases. Therefore, the PTC new phases only span a subset of the 0–1 range. To our knowledge, Demir et al. 1997 is the only published example with figures that illustrate the shifted limit cycle (set of new phases) of a perturbed model neuron.

Biological oscillators can show both type 0 and type 1 phase resetting. The transitions between type 1 and type 0 phase resetting, however, are difficult to observe experimentally (Krogh-Madsen et al. 2012). Spiking neurons tend to exhibit type 1 phase resetting (Netoff et al. 2005; Preyer and

Butera 2005; Schultheiss et al. 2010; Wang et al. 2013), but type 0 resetting is possible (Perkel et al. 1964; also see the list in Winfree 2000, p. 116, for type 0 resetting in physiological systems). Bursting neurons can show type 1 phase resetting with very weak inputs, but tend to show type 0 phase resetting (Prinz et al. 2003; Sieling et al. 2009).

Phase Resetting Theory in Computational Neuroscience

The application of PRCs in computational neuroscience is most often to infer synchrony among a population of neurons. With such approaches, either weak coupling or pulsatile coupling is typically assumed. A fundamental assumption underlying weak coupling is that perturbations to the limit cycle are sufficiently small (Ermentrout and Kopell 1984) and that increased perturbation size increases the PRC linearly (Schwemmer and Lewis 2012). The pulsatile coupling framework makes no restrictions on the size of the

perturbation as long as the oscillator returns to its limit cycle by the time the next input is received (Oprisan et al. 2004; Canavier and Achuthan 2010). The weak coupling assumptions, and the definition of weak, are fundamentally distinct from the geometrical terms defined by Winfree. We refer to the notions of weak and strong here as *mathematically weak* (or strong) and those by Winfree as *geometrically weak* (or strong).

In networks with weak coupling, the assumption that oscillator perturbations be suitably small means the phase resetting is mathematically weak. Systems with mathematically weak phase resetting show geometrically weak type 1 phase resetting. In contrast, systems with geometrically strong type 0 phase resetting will not show mathematically weak phase resetting. Geometrically weak type 1 phase resetting can be either mathematically strong or weak.

The geometric classification of type 1 or type 0 phase resetting is also distinct from the type I or type II phase resetting classifications common in the computational neuroscience literature (Rinzel and Ermentrout 1989). There is little to no correlation between the two classification schemes. This classification is based on the relationships between applied current and steady-state spike frequency (Hodgkin 1948), which are also related to the bifurcation associated with the modeled fixed point (Rinzel and Ermentrout 1989).

Discussion

Geometric phase resetting provides an effective classification scheme for neural systems. The geometric method is similar to the pulsatile coupling regime (Krogh-Madsen et al. 2012); such resetting is easily realizable experimentally but pulsatile coupling assumptions require that the same types of inputs present in the coupled system must be used to measure the PRC if the PRC is to have any predictive power. Geometric phase resetting classification is applicable over a wider range of inputs than is phase resetting based on weakly coupled oscillators; in turn, coupled system phase predictions using weak coupling theory can be independent of input type, provided those

inputs are small (Krogh-Madsen et al. 2012). Geometric and mathematical resetting are therefore complementary approaches to understand patterned activity in neural systems.

Definition

A neural population model pictures the cortex as a continuum of excitable tissue comprised of

densely interconnected excitatory and inhibitory neurons, with cortical activity encoded as population-average firing rates. For certain ranges of cortical parameters, such models can exhibit multistability, with access to multiple equilibrium (homogeneous and stationary) and non-equilibrium (patterned or dynamic) spatiotemporal states. These distinct states may be identified with particular phases of normal and pathological brain activity such as wakefulness, anesthetic coma, and seizure. Transitions between states can be induced by variations in a control parameter such as neurotransmitter concentration and subcortical stimulation and can be likened to the thermodynamic phase transitions (e.g., melting, freezing) of physical science.

Detailed Description

Equilibrium Phase Transitions

The underlying mechanisms of commonly observed thermodynamic phase transitions – such as water freezing and ice melting – can be explained using the theory of equilibrium statistical mechanics developed in the late nineteenth and early twentieth centuries. State variables, such as pressure, temperature, and specific volume (inverse density), are linked by an equation of state that maps out a distribution or manifold of equilibrium coordinates as illustrated in Fig. 1. Each point on the manifold corresponds to local minimum of free energy and so acts as an “attractor” for the system. The different regions correspond to the different phases (gas, liquid, solid). Phase transitions occur when temperature and pressure are changed sufficiently to force the system to move from one equilibrium phase to another.

Such equilibrium phase transitions are known to exhibit universal properties – such as power law divergences in length and timescales – at the critical point. These divergences arise from markedly increased sensitivity to perturbations that manifests as large, slow spatial and temporal fluctuations in an order parameter (such as density), a phenomenon referred to as critical slowing down.

In the brain, the transition from normal wake to deep sleep – either natural or anesthetic drug induced – can be regarded as a phase transition between distinct brain states. In both cases, there is a surge in low-frequency cortical activity as the point of transition is closely approached, suggesting onset of critical behavior. For the anesthetic transition, this unexpected and paradoxical transient boost in EEG power at (or near) the moment of loss of consciousness is known as the drug biphasic effect (Kuizenga et al. 2001).

The anesthetodynamic phase transition was first modeled by Steyn-Ross et al. (1999) using a continuum of excitable tissue containing populations of densely interlinked excitatory and inhibitory neurons (see Encyclopedia entry ► “Anesthesia, Neural Population Models of” for further details). Anesthetic effect is modeled as a strengthened hyperpolarizing drive from inhibitory synapses, with the hyperpolarizing influence increasing with drug concentration. This model predicts that the manifold of equilibrium states can contain a reentrant fold (see Fig. 1b) in which the upper (high-firing) and lower (low-firing) stable nodes are separated by

an unstable mid-branch saddle. A drug-induced trajectory along the upper branch will eventually collapse to the lower branch, and this downward jump is supposed to represent the transition into anesthetic unconsciousness. Close to transition, surges in low-frequency EEG power are interpreted as a form of critical slowing arising from close approach to the saddle-node annihilation point.

Nonequilibrium Phase Transitions

The transition between two stable phases of brain activity (e.g., from wake to drug-induced sleep during anesthetic loss of consciousness) is characterized as an *equilibrium phase transition* if the cortical state changes from one spatially uniform stationary state on the equilibrium manifold to another. Alternatively, the cortex may undergo a *nonequilibrium phase transition* in which the system breaks the symmetry of the homogeneous stationary state by spontaneously evolving to a qualitatively different kind of state that is oscillatory in time or patterned in space. The formalism describing these kinds of symmetry-breaking transitions was developed by the Brussels group

Phase Transitions, Neural Population Models and, Fig. 1 Comparison between the manifold of equilibrium states of matter for a pure substance (*left*) and the equilibrium states of activity for a homogeneous cortical model (*right*). If gas and liquid states of the substance are equivalent to high- and low-firing states of the cortex, then thermodynamic pressure, temperature, and specific volume are roughly analogous to inhibitory drive, excitatory drive, and cortical firing rate (Q_e), respectively. At the

critical point in (a), gas and liquid become indistinguishable. CP marks the corresponding coordinate in (b) at which high- and low-firing states of the cortex merge continuously. At lower values of cortical excitation, the folded region allows the cortex to access multiple steady states (a modified from http://en.wikipedia.org/wiki/File:PVT_3D_diagram.png under Creative Commons license; b modified from Steyn-Ross et al. (2013) with permission of the authors)

led by Nicolis and Prigogine (1977) with their work on reaction–diffusion chemical systems such as the Brusselator, demonstrating emergence of temporal oscillations (Hopf bifurcation) and spontaneous pattern formation (Turing bifurcation).

Many cortical researchers have investigated nonequilibrium phase transitions and self-organization in neural population models. In addition to equilibrium transitions to fixed-point attractors, Wilson and Cowan (1972, 1973) also described far-from-equilibrium behaviors such as the emergence of limit cycles, traveling waves, and Turing structures. Ermentrout and Cowan (1979a, b) extended the continuum approach to include the rise and fall times of dendrite dynamics and the effect of spatially distributed (exponential and Gaussian) synaptic connections; they established connectivity conditions under which a homogeneous equilibrium state would destabilize in favor of spatially inhomogeneous oscillations (i.e., oscillating Turing patterns). In an extensive review, Ermentrout (1998) examined a wide range of nonequilibrium spatiotemporal behaviors that could be generated by a continuum model of the cortex, including global oscillations, wave fronts joining an excited state to a resting state, traveling and stationary pulses, traveling waves, and stationary Turing patterns. The Turing solution required a Mexican-hat connectivity with local excitation – to stabilize a narrow pulse of neural activity – and lateral (nonlocal) inhibition to prevent the excitatory activity from spreading.

Temporal Rhythms via Hopf Bifurcation

The emergence of specific cortical rhythms – such as the delta (≤ 4 Hz), alpha (8–12 Hz), and gamma (25–100 Hz) oscillations of human EEG – is commonly modeled as a Hopf instability that destabilizes the equilibrium state when a control parameter is varied. In their continuum model of electrical activity in the cerebral cortex, Rennie et al. (2000) showed that a weakly damped gamma resonance can become less damped (i.e., moves closer to resonance) as subcortical excitation is increased and that the gamma

damping is particularly sensitive to dendritic decay rates at inhibitory synapses.

Bojak and Liley (2005) argue that the alpha rhythm is a ubiquitous feature of human resting EEG, so they looked for evidence of a damped alpha resonance in order to tune the parameter settings for their continuum model; effectively, such tuning places the cortex close to a Hopf bifurcation in the alpha-frequency range.

Breakspear et al. (2005) investigated the emergence of absence seizure EEG patterns in a continuum thalamocortical model (due to Robinson et al. 2002) by varying the strength of the excitatory connection between cortex and thalamus. For a sufficiently strong coupling, the model exhibited a supercritical Hopf bifurcation to large-amplitude periodic dynamics of frequency ~ 3 Hz. Similar low-frequency seizure-like oscillations via Hopf bifurcation have been demonstrated by several other workers with purely cortical models that lack thalamic circuitry (Kramer et al. 2005; Liley and Bojak 2005; Wilson et al. 2006).

Spatial Patterns via Gap-Junction-Mediated Turing Bifurcation

In reaction–diffusion chemical systems, it is well known that the homogeneous equilibrium state can destabilize in favor of a spatially periodic patterned structures if the inhibiting agent diffuses more rapidly than the activator (Turing 1952). For the cortex, this corresponds to having long-range inhibition together with local excitation. Traditionally, this is arranged with a suitably shaped connectivity kernel describing the extent and strength of axonal connections between excitatory and inhibitory neural populations (Wilson and Cowan 1972), the implicit assumption being that neurons communicate exclusively via spikes acting at chemical synapses. However, it is evident that adjoining neurons can also communicate directly via diffusive electrical synapses (gap junctions), and these are ubiquitous throughout the central nervous system (Bennett and Zukin 2004). Since layer 1 of the cortex is predominantly (over 90%) comprised of inhibitory

neurons (Wozny and Williams 2011), conditions for Turing self-organization via strong long-range diffusive inhibition may be satisfied.

Steyn-Ross et al. (2007) introduced gap-junction diffusion into a continuum model of the cortex and established conditions for the emergence of stationary Turing patterns. In recent work, Steyn-Ross et al. (2013) investigated the interaction between a ~ 3 -Hz Hopf instability – brought on by anesthetic prolongation of the inhibitory chemical synaptic response – and the Turing spatial instability and found that the anesthetic coma state was characterized by a slow-wave oscillation that was chaotic in space and time. They postulated that a similar Turing–Hopf mechanism might underpin the slow oscillation of natural sleep.

Definition

Phase locking is a fundamental property of dynamical systems and implies an interaction between processes or system components and their state dynamics. Phase locking is statistically indicated by a nonrandom phase or phase difference distribution. Phase is a quantitative description of the state of a given process/component of the system and its temporal evolution. As such, phase is directly meaningful and comparable between different levels of study, and there it

differs, e.g., from signal amplitude of which the physiological meaning is dependent on experimental conditions. In computational neuroscience, phase is typically extracted from time series of neuronal activity. Phase locking can be estimated between two or more such time series and is then termed phase synchrony or phase correlation or between one time series and events such as sensory stimuli and is then termed stimulus locking. Finally, phase-locking methods can also be adapted to assess phase-amplitude and amplitude-amplitude coupling.

Detailed Description

Estimation of Phase

To explicitly represent frequency-band-limited phase and amplitude dynamics, most real-valued continuous signals can be transformed by filtering to a complex form. A popular choice is to convolve the signal with a complex wavelet, such as the Gabor or Morlet wavelet (Sinkkonen et al. 1995; Tallon-Baudry et al. 1996). In applications where the filter yields real-valued output, the complex form can be obtained by finding the imaginary part with the Hilbert transform. For segments of stationary signals, the phase estimation can be achieved with spectral measures as well, such as with the Fourier transform. These three approaches are formally equivalent (Bruns 2004) although spectral methods yield constant-sized frequency bins, while wavelets can be scaled with frequency to give a constant time-frequency resolution.

Let us denote the filtering operation with a center frequency f generically with the operator T_f so that the filtered signal $x(t, f)$ is obtained from the original signal $x_o(t)$ by

$$\begin{aligned} x(t, f) &= T_f[x_o(t)] \\ &= a_x(t, f) e[i\theta_x(t, f)], \end{aligned} \quad (1)$$

where i is the imaginary unit and $a_x(t, f)$ denotes the amplitude and $\theta_x(t, f)$ the phase of $x(t, f)$ (Fig. 1a). An array of such time series will be denoted by $X(t, f) = [x_f(t, f)] = A_x(t, f) e[i\Theta_x(t, f)]$, where

$j = 1 \dots n_s$ and n_s is the number of sensors or sources. Comparable phase time series can also be produced from point process time series (Rosenblum et al. 2004).

Definition of Phase Difference

With the phase estimates, one can either proceed directly to phase-locking estimation when the aim is to study phase locking of neuronal activity to specific event or further evaluate *phase differences* to examine interactions between time series.

The generic $n:m$ -phase difference ω_{nm} of signals x and y (Tass et al. 1998) is given by

$$\omega_{n,m} = n\theta_x - m\theta_y, \quad (2)$$

where the small integers n and m determine the frequency ratio $nf_x = mf_y$ of filters $\mathbf{T}_{f_x}$ and $\mathbf{T}_{f_y}$. For assessing the classical within-frequency phase synchrony, $n = m = 1$. Hence, for frequencies of a single sample of each signal against each other's signal is given by f_x and f_y , the $n_s \times n_s$ -sized pairwise phase difference matrix $\Phi_{n:m}$ the complex outer product, $\otimes$, so that

$$\Phi_{n,m}(t, , f_x, f_y) = (X/|X|)^n \otimes (Y/|Y|)^{*m}, \quad (3)$$

where the asterisk $*$ denotes the complex conjugate.

The phase difference can also be used to represent more complex state relationships such as amplitude-phase interactions, “nested oscillations” that are characterized by the phase locking of the amplitude envelope of a faster oscillation with the phase of a slower oscillation. The phase difference matrix, Φ_{AP} for nested oscillations is given by filtering the amplitude envelopes A_x of the faster oscillation at f_x with the filter $\mathbf{T}_{f_y}$ that was used to obtain the slower oscillation at $f_y < f_x$ (Vanhatalo et al. 2004).

$$\Phi_{AP} = [\mathbf{T}_{f_y}(A_x)/|\mathbf{T}_{f_y}(A_x)|] \otimes (Y/|Y|)^*. \quad (4)$$

It is important to note that this quantification of the nonuniformity of Φ_{AP} with a phase-locking value (see below) assumes a unimodal distribution of the fast oscillation amplitudes along the

slow oscillation phase. An interaction in which the amplitude of the fast oscillation peaks twice, or more formally m times during the slow cycle, can be explicitly assessed as a $1:m$ -amplitude-phase interaction. Here the amplitude envelopes A_x are filtered with a filter $\mathbf{T}_{mf_y}$ at frequency mf_y , and then the corresponding metric, Φ_{AmP} is given simply by

$$\Phi_{AmP} = [\mathbf{T}_{2f_y}(A_x)/|\mathbf{T}_{2f_y}(A_x)|] \otimes (Y/|Y|)^{*m}. \quad (5)$$

Φ_{AmP} is quantifiable with the phase-locking value. Alternatively, $1:m$ -amplitude-phase coupling can be implicitly assessed with Φ_{AP} and a histogram-based statistic (see below).

Characterization of amplitude dynamics with phase differences and circular statistics can be further extended also to amplitude-amplitude interactions by filtering the amplitude envelopes A_x and A_y to a slower frequency band $f_z < f_x, f_y$ with $\mathbf{T}_{f_z}$. Now the phase difference matrix, Φ_{AA} , is

$$\Phi_{AA} = [\mathbf{T}_{f_z}(A_x)/|\mathbf{T}_{f_z}(A_x)|] \otimes [\mathbf{T}_{f_z}(A_y)/|\mathbf{T}_{f_z}(A_y)|]^*. \quad (6)$$

The advantage of characterizing amplitude interactions with phase estimators is that their phase dynamics are independent of variability in the absolute amplitudes, and hence large amplitude events do not exert a strong bias like they do in cross-correlation analyses, for example.

Quantification of Phase Locking: The Phase-Locking Value and Alternative Measures

With the phase or phase difference data, the presence of statistically significant phase locking can be assessed with a number of circular statistics. The most common of them is the phase-locking value/factor (PLV, PLF) that is given by means of the complex phases (Jervis et al. 1983; Sinkkonen et al. 1995).

$$\text{PLV} = n_t^{-1} \left| \sum \Phi \right|. \quad (7)$$

Phase-Locking Methods, Fig. 1 PLV and imaginary PLV (iPLV) measure the strength of phase correlation but are biased by linear signal mixing. (a) Real parts ($x(t)$ and $y(t)$) and phases ($\Theta_x(t)$ and $\Theta_y(t)$) of two-phase coupled signals in the absence ($m = 0$) and presence ($m = 0.4$) of linear mixing where $x_{\text{mixed}} = x + my$ and $y_{\text{mixed}} = y + mx$. Linear mixing biases the phase difference between the

signals toward zero. (b) Phase difference distribution between signals $x(t)$ and $y(t)$ in the absence ($m = 0$) and presence ($m = 0.4$) of linear mixing. The phase difference of the simulated coupling between the signals was -0.3π . (c) PLV and iPLV defined graphically as the absolute value and imaginary part, respectively, of the mean of complex phase values on the unit circle

where n_t is the number of Φ samples pooled across trials and/or time (Fig. 1b, c). PLV is 1 for perfect coupling (delta-function phase distribution) and approaches 0 for a uniform phase distribution when $n_t \rightarrow \infty$. If the Φ samples are independent and the marginal phase distributions are uniform, the no-interaction null hypothesis is characterized by uniformly distributed Φ and can be tested with the Rayleigh test. When Φ are pooled across time, i.e., when the independence condition is not met because of redundancy and/or when the underlying process is not sinusoidal (see Nikulin et al. 2007), surrogate data are needed for statistical testing.

Five characteristics of PLV warrant attention. First, PLV is biased, i.e., positively dependent on the number of samples (Vinck et al. 2010; Aydore et al. 2013). Hence, if two conditions are to be compared, the number of samples must be equalized. Alternatively, a similar but unbiased metric, pairwise-phase consistency (Vinck et al. 2010; see also squared PLV in Aydore et al. 2013) can be used, but its computational cost scales with $n_s^2 n_t^2$, whereas the cost of PLV is proportional only to $n_s^2 n_t$.

Second, PLV is appropriate only for unimodal phase distributions. The nonuniformity of arbitrary distributions can be estimated with Shannon entropy and conditional probability-based indices for phase (difference) histograms (Tass et al. 1998).

Third, 1:1-phase (and also amplitude) correlations estimated with PLV are influenced by linear mixing such as volume conduction in electrophysiological recordings, which leads to inflated numbers of false-positive observations (see Fig. 1b, c). This problem can be partially solved by noting that linear mixing always has a zero-phase-lag influence, which is fully captured by the real part of PLV or that of coherence, and that true neuronal interactions may often involve a conduction-delay-related phase lag. Measures such as imaginary coherence (Nolte et al. 2004), the imaginary part of PLV, and weighted phase-lag index (Vinck et al. 2011) ignore the real part of the complex phase differences. These measures are hence insensitive to linear mixing while revealing the phase-lagged interactions. The disadvantages of these approaches include insensitivity to true near-zero-phase-lag interactions and the

dependence of the measure value on the phase difference per se in addition to the strength of the interaction.

Fourth, PLV is a measure of correlation and does not disclose causal relationships or the lack thereof between the signals. Directional phase interactions can be estimated with histogram-based phase transfer entropy without sample-size or linear mixing bias (Lobier et al. 2014).

Fifth, PLV among all other interaction metrics is crucially dependent on the signal-to-noise ratio of the phase estimate. Hence, albeit phase is mathematically independent of amplitude, the accuracy of phase estimates in noisy signals with variable amplitudes will be dynamically dependent on the amplitude. When making inferences about differences in phase locking, one needs to consider the putative contribution of concurrent differences in signal-to-noise ratio (Palva et al. 2010).

Definition

Phototransduction biophysics comprises intracellular molecular reactions and ion fluxes through ion channels on the photoreceptor membrane that converts light into an electrical signal. Phototransduction biophysics serves the purpose of counting photons and integrating these counts to an estimate – a macroscopic voltage response – of light changes from a small area of visual space. To do this task well in vastly varying light conditions, photoreceptors rely upon stochastic adaptive sampling of light information.

Detailed Description

Basic Structure of Photoreceptor Cells

Photoreceptor cells of most animals are highly polarized, consisting of light-sensitive and light-insensitive parts (Fig. 1). The light-sensitive part

is derived either from cilia or microvilli (Fain et al. 2010), forming a specialized light guide, such as the vertebrate rod/cone outer segment or fly photoreceptor rhabdomere, which facilitates directional photon capture along its longitudinal axis. Membrane elaborations – discs in rods or microvilli in fly photoreceptors – are enriched with the visual pigment protein rhodopsin. This absorbs light and activates a G-protein-based transduction cascade, bringing about the opening or closing of ion channels. Conversely, a photoreceptor's light-insensitive parts, which in vertebrate rods/cones form the inner segment, contain the cell body, axon, and synaptic machinery to transmit the resulting electrical signals to the retina network.

Microvilli Are Sampling Units

In a photoreceptor of the fruit fly (*Drosophila melanogaster*), each of its ~30,000 microvilli

Current Biology

Phototransduction Biophysics, Fig. 1 Phototransduction biophysics. Ciliary and microvillar photoreceptors. Photoreceptor types in principal eyes illustrated as

ciliary (red) or microvillar (blue). Mammals and other vertebrates have ciliary photoreceptors (rods and cones). (From Fain et al. (2010))

Phototransduction Biophysics, Fig. 2 Phototransduction biophysics, *Stochastic adaptive sampling in a Drosophila photoreceptor*. Photons are sampled by a population of 30,000 microvilli, stacked layer by layer on one side of the photoreceptor soma, forming the light-guiding

rhabdomere. In the microvilli, the rate, size, and speed of their photon-evoked elementary responses (bumps or samples) vary stochastically yet adapt continuously, integrating to a consistent (anti-aliased) macroscopic response

can be considered to be a photon counting or sampling unit (Fig. 2). Within a microvillus, following absorption of one photon by a single rhodopsin molecule, the phototransduction cascade culminates in the opening of ~ 15 TRP/TRPL channels (transient receptor potential and TRP-like channels; Hardie and Postma 2008). The resulting influx of calcium, magnesium, and sodium ions generates a quantum bump (sample). Although the exact mechanism of how TRP/TRPL channels are gated is still unclear, most aspects of microvillar phototransduction are known in sufficient detail (Hardie and Postma 2008; Hardie 2012; Hardie and Franze 2012) to allow the construction of molecularly explicit, stochastically operating computational models that accurately simulate the encoding of visual information (Song et al. 2012). The close correspondence between intracellular recordings and model simulations further suggests that vision benefits from stochasticity in phototransduction

biophysics, with variable samples of microvilli summing up largely invariable responses to natural light patterns at different conditions (Faivre and Juusola 2008; Song et al. 2012).

Basic Rules of How a Photoreceptor Samples Light Information

A *Drosophila* photoreceptor is an imperfect photon counter that, nonetheless, produces highly reproducible macroscopic responses. Its responses to light stimuli can be largely predicted by these basic counting rules:

- A single microvillus (sampling unit) can produce only one bump (sample) at a time (Howard et al. 1987; Hochstrate and Hamdorf 1990; Pumir et al. 2008; Song et al. 2012).
- After producing a bump, a microvillus remains refractory (unavailable to sample) for up to

hundreds of milliseconds; during this period, it fails to respond to other photons (Hochstrate and Hamdorf 1990; Scott et al. 1997; Mishra et al. 2007; Liu et al. 2008).

- Bumps from up to 30,000 microvilli integrate to yield the macroscopic response.
- Microvilli availability sets a photoreceptor's maximum sample rate (bump production rate), adapting its macroscopic response to a light stimulus (Howard et al. 1987).
- Global calcium accumulation and membrane voltage affect samples of all microvilli. These global feedbacks strengthen with brightening light to reduce the size and duration of bumps, adapting the macroscopic response (Wong and Knight 1980; Wong et al. 1982; Juusola and Hardie 2001b).

Phototransduction Reactions: From Photon Absorption to a Bump

Phototransduction in *Drosophila* is a canonical G-protein-coupled phospholipase C-based cascade (Hardie and Postma 2008; Yau and Hardie 2009; Hardie 2012). Essential elements of the cascade including the channels are localized within a microvillus (Fig. 3), which together with its ~30,000 neighbors form the light-guiding rhabdomere.

As in all photoreceptors, the cascade is initiated by absorption of a photon by a chromophore (3-OH 11-*cis* retinaldehyde) covalently attached to rhodopsin (R). Photoisomerization of the 11-*cis* retinal to the all-trans configuration by a single photon converts R to the active metarhodopsin state (M), which catalytically activates a heterotrimeric Gq-protein releasing the active Gq α subunit. About 5–10 Gq α subunits are released by each activated M within the same microvillus during the brief but variable latency period, and diffuse in the plane of the membrane before binding to and activating a phospholipase C (PLC) molecule. Each of the 5–10 PLC molecules (Fig. 3) thus activated and then hydrolyzes the minor membrane phospholipid, PIP₂, at a rate of ~1000 molecules per second, causing a physical contraction of the

microvillar membrane as well as yielding inositol triphosphate (InsP₃), diacyl glycerol (DAG), and a proton.

Although still debated, the most recent evidence suggests that it is the combination of membrane contraction and proton release that then results in the gating of the Ca²⁺ permeable TRP (and TRPL) light-sensitive channels (Huang et al. 2010; Hardie and Franze 2012). Powerful positive feedback mediated by Ca²⁺ influx via the first activated TRP channel rapidly facilitates activation of the remaining channels in the microvillus. This floods the microvillus with up to ~1 mM Ca²⁺, rapidly terminating the response by Ca²⁺-dependent negative feedback at multiple targets including the channels themselves. The final electrical response to a single effectively absorbed photon is a ~10 pA quantum bump (Fig. 4a), representing the opening of most of the ~20 TRP channels in a single microvillus.

The macroscopic light-induced current (LIC) represents the summation of the quantum bumps of variable sizes (Fig. 4b) and timings (Fig. 4c), independently generated over the 30,000 microvilli.

Why Some Absorbed Photons Fail to Be Counted?

In a microvillus, the likelihood, size, and timing of a new bump depend upon the success, stochasticity, and finite speed of phototransduction reactions, all partly affected by the history of past bumps in the same microvillus and global Ca²⁺ levels integrated from bumps across the whole cell (Fig. 4a). In darkness, virtually every absorbed photon causes a bump (nearly 100% quantum efficiency), but with brightening illumination, the quantum efficiency of a microvillus decreases. Rarely, the cascade molecules may fail to activate their upstream targets and the signal dies. More often, the reactions stop prematurely because the photons arrived before the refractory period (50–200 ms) of the last bump had faded. Here, intra-microvillar calcium provides sequential positive and negative feedbacks to multiple targets, amplifying the signal

Phototransduction Biophysics, Fig. 3 Phototransduction Biophysics, Each microvillus contains a full transduction cascade, which generates variable bumps or failures to absorbed photons. Left side: molecular participants in microvillar phototransduction reactions. *M** meta-rhodopsin, *C** Ca^{2+} -dependent feedback, which acts as negative feedback to multiple targets, *D** DAG, *P** G-protein-PLC complex. Right side: the corresponding

reactions, R₁–R₁₂ (indicated by black arrows), as used in the stochastic model (see Eqs. below) and in Fig. 4a. Red dotted arrows indicate negative feedbacks; green dotted line, positive feedbacks. In this schematic, DAG? stands for the yet unresolved gating mechanism that includes production of DAG, InsP₃, proton, and physical microvilli contraction (Adapted from Song et al. (2012))

and accelerating response speed (Hardie and Postma 2008).

Biophysical models (Pumir et al. 2008; Song et al. 2012) indicate that as soon as a bump is generated, the negative feedback holds the microvillus in a state of inhibition during which it cannot respond to light. This refractory period represents a balance between the positive and negative feedbacks. It ends when the positive feedbacks outgrow the relaxing negative feedbacks and ultimately set the maximum sample

rate (bump production rate) of the microvillus (Hochstrate and Hamdorf 1990; Scott et al. 1997; Mishra et al. 2007; Liu et al. 2008).

How Changes in Sampling Result in Adapting Macroscopic Responses?

Adaptation in macroscopic response (Fig. 5a) to continuous light is mostly caused by reduction in the (i) number and (ii) size of samples over time.

Phototransduction Biophysics, Fig. 4 Phototransduction Biophysics, *Reactions inside a microvillus are modeled in a stochastic framework, with known molecular interactions, using physiologically measured parameters.* (a) Simulations show how a microvillus generates elementary responses (bumps) to captured photons; after a “dead time,” 5–15 TRP channels open, mediating Ca^{2+} and Na^+ influx into the microvillus. Ca^{2+} -dependent feedback (red) provides negative feedback, which prevents new bumps until the feedback is low. * = G^* activation failed;

** = negative feedback blocked two photon activations. $[C^*]$; decay phase is longer than the real refractory period, which represents a balance between the feedbacks; the positive feedback can outgrow the negative one in the middle of $[C^*]$ decay. Thus, a bump can be generated without C^* being zero (e.g., the third bump). (b) Average recorded and simulated bumps are similar. The bump current is given by Eq. 1. (c) Latency distributions of simulated and real bumps are similar. (Adapted from Song et al. 2012)

(i) At the stimulus onset, a large fraction of the microvilli is activated simultaneously but then becomes refractory (Fig. 5b). This leaves a smaller fraction of the microvilli to respond to the next photons in the stimulus until more microvilli become available again. Therefore, the number of activated microvilli (samples) first peaks, followed by a rapid drop before settling to a steady state as photon arrivals and refractory periods balance.

(ii) If all bumps were identical, then the macroscopic current would simply represent the number of activated microvilli at a given photon rate, with a flattened steady-state response. However, real light-induced currents show decaying trends toward lower plateau levels. This is because bumps adapt (Fig. 5c), becoming smaller and briefer with brighter backgrounds (Wong and Knight 1980; Wong et al. 1980, 1982; Juusola and

Phototransduction Biophysics, Fig. 5 Phototransduction Biophysics, Availability of microvilli and their adapting bumps shape responses to light. (a) LIC to a bright pulse recorded from dissociated R1–R6 *Drosophila* photoreceptors (R1–R6 are the six outer photoreceptors in a single ommatidium) during whole-cell patch clamp (black) and a simulated LIC (red) to the same stimuli. LIC is shaped by the number of activated microvilli (b) and negative feedback, which reduces the size of the bumps they produce (c). (b) Output of 30,000 microvilli modeled, showing the fractions of used (refractory) and activated microvilli and their sums in the model simulations to

reproduce (a). (c) Dotted line shows the ratio of the normalized LIC (a) and the number of activated microvilli (b), which represents the effect of a reduction in bump waveform on LIC as a function of time (whereas the refractory period affects microvilli usage). Bump size begins to diminish already after the first bumps, which shape the initial transient response. Time course of bump adaptation is approximated by a single exponential. In (a), most differences between the traces are due to a fixed (light adapted) refractory period distribution, which was used in the simulation

Hardie 2001b). This global negative feedback likely stems from Ca^{2+} -dependent inhibition due to light-induced calcium spread between microvilli via the cell body (Hardie 1996; Postma et al. 1999; Hardie and Postma 2008). This attenuates bump waveforms by progressively strengthening the negative feedback to multiple targets. Furthermore,

the resulting membrane voltage increase also compresses responses by reducing the electromotive force for the light-induced current across all microvilli (Song et al. 2012).

Thus, experiments and simulations suggest that reduction both in the number of samples (activated microvilli) and in their size (bump

waveforms) largely accounts for adaptation in the macroscopic response.

What Governs the Rate of Information Transfer of Macroscopic Responses?

The signal-to-noise ratio and rate of information transfer increase with the average sampling rate, which is the average number of samples per unit time. Thus, the more samples that make up the macroscopic response to a given light pattern, the higher is its rate of information transfer (Fig. 6). However, with more photons being counted by a photoreceptor at brightening stimulation, information about naturalistic light patterns in its responses first increases and then approaches a constant rate. This is because:

- (i) When more microvilli are in refractory state, more photons fail to generate bumps. As quantum efficiency drops, the equilibrium between used and available microvilli approaches a constant (maximum) bump production rate (sample rate).
- (ii) Once global calcium and voltage feedbacks saturate, they cannot make bumps any smaller and briefer with increasing brightness.
- (iii) After initial acceleration from the dark-adapted state, bump latency distribution remains practically invariable in different light-adaptation states (Juusola and Hardie 2001b).

Therefore, when sample rate modulation (i) and sample integration dynamics (ii and iii) of the macroscopic voltage responses settle (at intensities $>10^5$ photons/s in *Drosophila* R1–R6 photoreceptors; Fig. 6a–d), allocation of visual information in the photoreceptor's amplitude and frequency range becomes nearly invariable (Faivre and Juusola 2008; Song et al. 2012). Correspondingly, stochastic simulation closely predicts measured responses and rates of information transfer (Zheng et al. 2006, 2009; Gonzalez-Bellido et al. 2011; Song et al. 2012). Notably, when the microvilli usage reaches a mid-point (~50% level) (Fig. 6e), the information rate encoded by the macroscopic responses to natural

light intensity time series saturates (Song et al. 2012). This is presumably because sample rate modulation to light increments and decrements – which in the macroscopic response code for the number of different stimulus patterns (Juusola and de Polavieja 2003) – saturate.

Bump size, if invariable, does not affect the rate of information transfer – as long as the bumps are briefer than the stimulus changes they encode. Thus, like any other filter, a fixed bump waveform affects signal and noise equally (data processing theorem; Shannon 1948; Juusola and de Polavieja 2003; Song et al. 2012). But varying bump size adds noise; when this variation is adaptive (memory based), less noise is added (Song et al. 2012).

What Are the Coding Benefits of Global Feedbacks?

In bright light, global calcium and voltage feedbacks reduce bump amplitudes and durations, enabling more evenly encoded macroscopic responses that can utilize a smaller voltage range. This likely reduces a photoreceptor's energy consumption (Laughlin et al. 1998).

Together with the stochastic latency and refractory period distributions, the bump waveform regulates the size (gain) and speed (frequency range) of macroscopic responses (Juusola and Hardie 2001b; Faivre and Juusola 2008; Song et al. 2012). In very dim conditions, quantum efficiency is near 100% and the influence of global feedbacks is minimal. This leads to generation of large variable bumps with broad timing jitter, integrating macroscopic responses of high sensitivity. In bright conditions, conversely, quantum efficiency is $<1\%$ and global feedbacks are maximal. The outcome is smaller, less variable, and better synchronized bumps, which integrate to a macroscopic response of lower sensitivity. However, in large part due to the low-frequency dominated spectra of natural images ($1/f$), the macroscopic response waveforms to dim or bright natural light intensity time series are very similar (Faivre and Juusola 2008; Song et al. 2012).

In diurnal insect photoreceptors that have been tested both in dark- and light-adapted conditions

Phototransduction Biophysics, Fig. 6 Phototransduction Biophysics. In a fully light-adapted state, sample (bump) rate changes define the rate of information transfer of macroscopic responses. (a) Stochastic microvilli models can be set to use the corresponding average bump waveforms and latency distributions, estimated from the white-noise contrast experiments at different light levels, by refixing two model parameters: n_s (Eq. 7) for the bump shape and l_a (Eq. 8) for the latency distribution. (b) 100 superimposed responses (light gray) and the average signal to a repeated bright naturalistic stimulus (NS), and the corresponding simulations. (c) The NS activates microvilli stochastically with appropriate dynamics and statistics. Owing to largely low-frequency input ($1/f$ statistics), the number of activated microvilli is mostly responsible for the corresponding response waveforms (b). This encoding uses only a fraction of 30,000 microvilli (maximally $\sim 68\%$ for the repeated NS) because the NS contains long relatively dim periods, allowing refractory microvilli to return to the pool of available ones during stimulation. (d) Information transfer rate of photoreceptors (black)

and the model (gray) to the same NS at six different light levels. Recordings' lower information transfer at three brightest intensities can be attributed to damage, experimental noise, and intracellular pupil, which progressively filter out photons. At dim intensities, the effect of experimental noise and adaptation may be compensated by the synaptic network introducing new information from neighboring photoreceptors. Quantum efficiency (QE) of simulated photoreceptor output drops with brightening of the NS, while the information transfer approaches a constant rate. (e) Information transfer reaches maximum when about 50% of microvilli are in continuous use and is maintained, despite steep falloff in quantum efficiency (QE) at the brightest intensities (d). Inset: during a very bright NS, because of its $1/f$ statistics that contain interspersed darker periods, proportionally more microvilli recover than during light pulses (dotted lines) of equal mean intensity. A very bright pulse (10^6 photon/s) activates $\sim 99\%$ of microvilli at the beginning of stimulation, and their usage remains high throughout the pulse. Error bars show SD (Adapted from Song et al. 2012)

(Juusola and Weckström 1993; Juusola and Hardie 2001a, b; Faivre and Juusola 2008; Gonzalez-Bellido et al. 2011), the bandwidths of their membranes show higher cutoff frequencies than those of their light-induced currents. Thus, the global voltage feedback compresses – by reducing the electromotive drive of light-induced current (Song et al. 2012) – the responses without much influencing the frequency allocation of the transmitted information (Shannon 1948; Juusola and de Polavieja 2003).

In summary, global feedbacks perform important energy-efficient normalization processes. These enable variable samples and counts to add up to similarly shaped macroscopic voltage responses for natural light changes in different illumination conditions, paving the way for perceptually invariant neural representations of visual objects.

What Are the Benefits and Costs of Adaptive Stochastic Sampling?

Stochastic sampling is not only an elegant light-adaptation strategy but may also represent a novel, generic solution to the temporal aliasing problem. It scatters high-frequency information into broadband noise rather than generating the false patterns produced by regular sampling (Leneman 1966). Thus, variable sampling times and sample sizes prevent distortions or artifacts in reconstruction of macroscopic responses from the original (continuous) light patterns. Similarly, topological disorder of photoreceptors in retinae likely provides anti-aliased sampling of spatial (Yellott 1982) and chromatic (Wardill et al. 2012) information from visual scenes. Intrinsic biophysical heterogeneity in neuron populations can further increase information content and robustness of their collective spatiotemporal signal (Heimonen et al. 2006; Padmanabhan and Urban 2010).

The trade-off of stochastic sampling is broadband noise (Leneman 1966; Dippe and Wold 1985). However, in fly photoreceptors – due to

global feedbacks that carry memory of the past events – such noise is reduced by adapting the sample sizes to the ongoing light stimulation. This accounts for about 10% improvement in the rate of information transfer, in comparison to sampling the bumps randomly from the same distribution (Song et al. 2012). Noise is further reduced when signals from neurons converge, e.g., when macroscopic responses of photoreceptors, which sample light from the same point, are pooled in synaptic transmission to interneurons (Zheng et al. 2006).

Specifically in fly photoreceptors, adaptive stochastic sampling has been shown to (Song et al. 2012):

- Resist saturation – It is hard to knock out all microvilli at once, as there are always some returning to the pool of available ones in any one moment.
- Improve the signal-to-noise ratio of macroscopic responses, in comparison to corresponding estimates that are sampled randomly (without memory) from the same bump waveform distribution.
- Reduce oscillations in macroscopic responses to sudden stimulus changes.
- Utilize microvilli and the amplitude range of photoreceptor output more evenly. Notably, a macroscopic response, in which every voltage level is utilized equally often, would have the highest information content (Shannon 1948; Zheng et al. 2009).
- Promote equalizing of contrast information transfer in different light conditions.
- Evoke similarly shaped responses in different light conditions.
- Enhance responses to novel stimuli (Juusola and de Polavieja 2003). Events which generate the largest changes in microvilli activation (sample rate modulation bump increments or decrements) with respect to the ongoing average are represented by macroscopic responses with the highest information content (Song et al. 2012).

Photoreceptor Structure Defines Its Encoding Performance

Models of different fly photoreceptors indicate that their structures and biophysical makeup are intrinsically linked to the neural signaling they carry out (Song et al. 2012). Thus, differently shaped photoreceptors of different species presumably evolved to match the visual requirements of their lifestyle. A photoreceptor's maximum information transfer rate cannot be increased beyond its structural limits, hardwired in the maximum number microvilli and in their maximum bump production rate (Fig. 7). Photoreceptors with the most and fastest microvilli in principle provide the best vision. However, this comes at a price: more microvilli increase plasma membrane's capacitance and potentially its time constant. The larger (slower) time constant can only be offset by larger conductances, ultimately consuming more ATP (Laughlin et al. 1998; Fain et al. 2010).

Appealing analogy: Sir Francis Galton realized that the mean of variable samples, reported independently by honest observers, provides the best estimate of the witnessed event (Galton 1907). In fly photoreceptors, the observers are the tens of thousands of microvilli. Each of them has either encountered photons recently or not. A microvillus that absorbs a photon casts an independent vote on how important (surprising) that event is, given the past light history. Accordingly, the weighted average of all the sampled simultaneous votes (macroscopic response) provides a reliable (non-aliased) neural estimate of the ongoing light signal. This information matches the visual requirements of the animal, as embedded in its hardwired photoreceptor structures and stochastic phototransduction biophysics (Gonzalez-Bellido et al. 2011; Song et al. 2012).

Biophysical Photoreceptor Model

A biophysical model of a *Drosophila* photoreceptor that can generate realistic responses to time series of light intensities contains four modules (Song et al. 2012):

- (i) Random Photon Absorption Model: regulates photon absorptions in each microvillus, following Poisson statistics.
- (ii) Stochastic Bump Model: stochastic biochemical reactions inside a microvillus capture and transduce the energy of photons to variable bumps or failures.
- (iii) Summation Model: bumps from 30,000 microvilli integrate to the macroscopic light-induced current (LIC) response.
- (iv) Hodgkin-Huxley (HH) Model of the photoreceptor plasma membrane: transduces LIC into a voltage response.

This modeling approach is robust and does not require full knowledge of all molecular players and dynamics in the phototransduction process. From a computational viewpoint, the exactness of the simulated molecular interactions is not important. As long as the photoreceptor model contains the right number of microvilli, each of which is a semiautonomous sampling unit, and their stochastic bump dynamics (average waveforms, latency distribution, and refractory period) approximate those in the real recordings, it will sample and process information much like a real photoreceptor (Song et al. 2012).

Random Photon Absorption Model

- Input: the number of photons absorbed by the rhabdomere in each 1 ms time interval
- Output: the number of photons absorbed by each microvillus

With photon absorptions following Poisson statistics (Hochstrate and Hamdorf 1990), variable numbers of photons are absorbed by each microvillus in the rhabdomere. Because the bump/photon ratio in each microvillus changes with the number of photons it absorbs, this model is needed for generating a realistic light input for each microvillus.

Key assumptions:

- Each microvillus absorbs photons independently with all microvilli having the same

Phototransduction Biophysics,

Fig. 7 Phototransduction Biophysics,

Photoreceptor models of adaptive sampling behave like real photoreceptors. (a–c)

Outputs of *Drosophila*, *Calliphora*, and *Coenosia* photoreceptors, respectively, were simulated by stochastic models. The microvilli numbers were fixed to match those of the real cells, and their average bump waveforms (dark red) and latency distributions (gray)

were approximated from *in vivo* recordings by adjusting the negative feedback strength within their microvilli, by refixing two global negative feedback parameters: n_s and la . These photoreceptor models' voltage responses (red)

to the repeated presentations of a naturalistic stimulus (NS) pattern behave as their real counterparts (black).

Lower insets show the corresponding refractory periods (inter-bump intervals, yellow), generated by the microvilli of the models to the NS. Information transfer rates (right) of the simulated responses follow those of the real recordings.

(Adapted from Song et al. 2012)

absorption probability. These assumptions eliminate the role of rhabdomere topology, simplifying calculations. In rhabdomeres, microvilli taper, with their photon absorption probabilities at the bottom being likely less

than those at the top. Nonetheless, because simulations pair well with the experimental results, probabilistic scaling of the photon flux (through the tapering microvilli) is not critical.

As there are $\sim 30,000$ microvilli in a *Drosophila* photoreceptor rhabdomere, if the light input contains N_{ph} photons in the given time interval (1 ms), the average number of photons a single microvillus can absorb is $\lambda_M = N_{ph}/30,000$. Following Poisson statistics, the fraction of microvilli that absorb k photons is $p(k) = \lambda_M^k e^{-\lambda_M} / k!$. Therefore, $30,000 \times p(k)$ microvilli can be uniformly drawn to absorb k photons at one time point, where $k < k_n$; k_n is the smallest number that satisfies $p(k_n) < 1/30,000$. This procedure iterates along the light time series with each microvillus obtaining an absorbed photon series to stimulate its phototransduction cascade.

Stochastic Bump Model

- Input: the number of photons absorbed by each microvillus
- Output: variable bumps generated by each microvillus

Stochastic phototransduction cascade models simulate known enzymatic reactions (Pumir et al. 2008; Song et al. 2012), generating variable bumps (samples) to absorbed photons. Bump series to sequential photon absorptions are needed for investigating continuous adaptation processes. Despite the many model parameters, adaptation can be regulated by two master parameters: n_s in Eq. 7 for bump shape and la in Eq. 8 for bump latency distribution. The model also includes a representation of $[Ca^{2+}]$ dynamics.

To account for the intrinsic variability in the reactions, where several molecular interactions occur at low numbers, the quantum bump model uses a stochastic simulation framework based on the Gillespie algorithm (Gillespie 1976).

Key assumptions:

- Because spontaneous bumps are very rare (Hardie and Postma 2008), reactions are assumed to be silent in the dark-adapted state.
- A well-mixed chemical system is assumed for simplicity. All the reaction pathways are decomposed into M unidirectional elementary

reaction steps R_μ . Each of these reaction steps is characterized by a momentarily defined stochastic reaction constant, c_μ , where $c_\mu \delta t$ ($\mu = 1, 2, \dots, M$) denotes the average probability that a particular combination of R_μ reactant molecules will react accordingly in the next infinitesimal time interval δt .

If h_μ is the total number of R_μ reactant pairs, then $a_\mu \delta t = c_\mu h_\mu \delta t$ is the average probability that reaction R_μ will occur during δt . By considering a discrete infinitesimal time interval, $(t, t + dt)$, during which 0 or 1 reaction occurs, dt and R_μ can be determined independently. When R_μ is chosen, the state vector $\mathbf{X}$ is updated with a state transition vector, $\mathbf{V}_\mu$. The procedure iterates until a termination criterion is satisfied, e.g., if the current simulation time, t , is larger than a preset value.

The molecules are counted when there are only a few in each microvillus. Otherwise, concentrations are used, calculated using the microvillus volume. In the equations or reactions, X is the number of molecules; X^* is the active state of X , and X_T the total number of corresponding molecules/channels inside a single microvillus. $[X]$ is the concentration; $[X]_i$ is intracellular concentration and $[X]_o$ the extracellular concentration. Rates of activation are denoted by κ and rates of deactivation by γ . Positive and negative feedbacks are f_p and f_n , respectively, and the local feedback strength parameter is h .

The signaling pathway is decomposed into a set of unidirectional reactions, R1, R2, R3, R4, R5, R6, R7, R8, R9, R10, R11, and R12 (indicated by arrows in Fig. 3, right side), each of which contains only unimolecular or bimolecular reactants:

Because the input is the number of absorbed photons, photon-activated rhodopsin (metarhodopsin, M^*) is incremented by 1 if one photon is absorbed in a microvillus.

In the unidirectional reactions:

- [R1](#) is the inactivation of metarhodopsin (M^*) by arrestin binding; ϕ indicates any reaction product, whose kinetics is not modeled. G-proteins can exist in multiple states. For simplicity, only the cycle through three states is modeled: $G_{\alpha}G_{\beta\gamma}GDP$ (G), $G_{\alpha}GTP$ (G^*), and $G_{\alpha}GTP-PLC$ (PLC^*).
- [R2](#) is the activation of G into G^* by M^* .
- In [R3](#), G^* binds to PLC and becomes an active G-protein-PLC complex (PLC^*).
- [R4](#) and [R5](#) represent the recycling process of G-proteins. [R4](#) is the conversion from $G_{\alpha}GTP$ to $G_{\alpha}GDP$ by GTPase activity of G^* , supposedly catalyzed by PLC^* . $G_{\alpha}GDP$ then rebinds to $G_{\beta\gamma}$ before it can be reactivated ([R5](#)).
- PLC^* hydrolyzes PIP_2 into DAG and IP_3 , generating the unknown excitation messengers for TRP/TRPL channels. In [R6](#), because of this

ambiguity, PLC^* is modeled to activate the supposed excitation messenger D^* directly.

- D^* excites TRP/TRPL channels T to their open states (T^*) in [R9](#) and is degraded in [R8](#).
- [R10](#) is the process of closing the open TRP/TRPL channels.
- [R11](#) is the binding of Ca^{2+} , which enters the microvillus through the open TRP/TRPL channels, to Calmodulin C^* . [R11](#) is a simplified first-order representation of the Ca^{2+} binding process, where in reality, 4 calcium ions bind to CaM to form C^* .
- [R12](#) is the release of Ca^{2+} from Calmodulin.
- Ca^{2+} -bound Calmodulin constitutes the feedback intermediate for regulating the reactions [R1](#), [R2](#), [R3](#), [R4](#), [R5](#), [R6](#), [R7](#), [R8](#), [R9](#), and [R10](#).

In these reactions and under voltage-clamped conditions, the light-induced current, I_{in} , is the product of T^* (the output for the phototransduction cascade) and I_{T^*} (the average single-channel current conducted by an open TRP/TRPL channel).

Assuming that, apart from Ca^{2+} , the molecular components cannot enter or leave the microvillus, the following mass balance equations hold:

$$T^* + T = T_T \quad (1)$$

$$CaM + C^* = C_T \quad (2)$$

$$PLC^* + PLC = PLC_T \quad (3)$$

$$G^*GDP + G + G^* + PLC^* = G_T \quad (4)$$

Using these mass balance equations, the number of state variables can be reduced and the state vector, $\mathbf{X}$, defined as

$$\mathbf{X} = [M^*; G; G^*; PLC^*; D^*; C^*; T^*] \quad (5)$$

The details of how the state transition matrix, $\mathbf{V}$, the number of reactant pairs, $\mathbf{h}$, and the stochastic reaction constant vector, $\mathbf{c}_{1 \times 12}$, are defined and calculated for each reaction, [R1](#), [R2](#), [R3](#), [R4](#), [R5](#), [R6](#), [R7](#), [R8](#), [R9](#), [R10](#), [R11](#), and [R12](#), are explained in Song et al. (2012).

Calcium Dynamics Ca^{2+} is an essential feedback signal in the phototransduction cascade. Ideally, Ca^{2+} should be included as one of the state variables. However, because Ca^{2+} changes up to 1000-fold during a bump, its dynamics is not included in the state vector (Eq. 5) but approximated by a deterministic approach (Fig. 4a) (Song et al. 2012). Otherwise, simulations via the Gillespie algorithm would become impractically slow.

Computations can be streamlined by using hybrid techniques (Resat et al. 2001; Haseltine and Rawlings 2002; Rao and Arkin 2003; Puchalka and Kierzek 2004; Salis and Kaznessis 2005). In general, Ca^{2+} dynamics is simulated by deterministic methods as a balance between net Ca^{2+} influx, Ca^{2+} uptake by calcium buffer, and Ca^{2+} diffusion to the cell body. The net Ca^{2+} influx (pA) is the difference between Ca^{2+} influx and Ca^{2+} extrusion through $\text{Na}^+/\text{Ca}^{2+}$ exchanger, where Ca^{2+} influx is estimated to constitute 40% of the total ion influx. Ca^{2+} extrusion through $\text{Na}^+/\text{Ca}^{2+}$ exchanger can be calculated from a simplified format of the $\text{Na}^+/\text{Ca}^{2+}$ exchanger model (Luo and Rudy 1994), given that the extracellular ionic concentrations are fixed and the cell is voltage clamped. To update Ca^{2+} quantities in the stochastic simulation framework, Ca^{2+} dynamics are assumed to be so fast that the quantities can be approximated by the steady-state values. Song et al. (2012) give the formulation of this approach and explain how to update Ca^{2+} dynamics in the simulations.

Positive feedback (indicated by green dotted lines in Fig. 3): f_p is formulated as a Hill function of $[\text{Ca}^{2+}]_i$ inside a microvillus:

$$f_p([\text{Ca}^{2+}]_i) = \frac{([\text{Ca}^{2+}]_i/K_p)^{m_p}}{1 + ([\text{Ca}^{2+}]_i/K_p)^{m_p}} \quad (6)$$

where K_p is the dissociation constant, i.e., $[\text{Ca}^{2+}]_i$, that provides half occupancy of Ca^{2+} binding sites for the channels and m_p is the Hill coefficient, describing the cooperativity of Ca^{2+} in exciting the channels.

Negative feedback (indicated by red dotted arrows in Fig. 3): f_n is formulated as proportional to a Hill function of $[\text{C}^*]_i$:

$$f_n([\text{C}^*]_i) = n_s \times \frac{([\text{C}^*]_i/K_n)^{m_n}}{1 + ([\text{C}^*]_i/K_n)^{m_n}} \quad (7)$$

where n_s denotes a global negative feedback strength parameter. This is one of the most important parameters in the model; it is the only parameter that is used to regulate the bump shape in our simulations (Fig. 7), whereas all the other kinetic parameters are fixed. K_n is the dissociation constant and m_n is the Hill coefficient for $[\text{C}^*]_i$. In reality, the affinity of $[\text{C}^*]_i$ might vary for different feedback targets, leading to different parameter values for K_n and m_n . However, for simplicity, it is assumed that the whole pool of available C^* binding sites have the same affinity properties and local feedback strengths are parameterized by h_* . This simplification provides a practical initial approximation, in the absence of more complete mechanistic knowledge concerning the different underlying processes. The related parameters (h_* , etc.) are listed in Song et al. (2012).

With the definitions of $\mathbf{V}$, $\mathbf{c}$, and $\mathbf{h}$, the time increment dt , during which the next reaction R_μ occurs, is determined as

$$dt = \frac{1}{la + a_s} \ln \left(\frac{1}{r_1} \right) \quad (8)$$

where r_1 is a uniformly distributed random number and a_s is the dot product between $\mathbf{c}$ and $\mathbf{h} \left(a_s = \sum_{\mu=1}^{\mu=M} c_\mu h_\mu \right)$. Apart from the parameter n_s in Eq. 7, la (or latency width regulator) is the only other critically important parameter in our model, affecting the latency distribution (Fig. 7). R_μ can be chosen so that Eq. 9 satisfies

$$\sum_{v=1}^{\mu-1} a_v < r_2 a_s \leq \sum_{v=1}^{\mu} a_v \quad (9)$$

where r_2 is a uniformly distributed random number and $a_v = c_v h_v$.

Simulating the Phototransduction Model The stochastic bump model can accommodate complex time series of photon inputs. When a new photon input arrives, the Gillespie algorithm is stopped and the molecule numbers are updated. As described above (Fig. 4), simulations clarify why a single microvillus can only produce one bump at a time, regardless of its photon input (see above) and how bumps from a single microvillus adapt, depending on its memory state of the photon input history.

The simulated bump series can be quantified by three bump parameters, namely, bump waveform (i.e., its amplitude and duration), latency distribution, and refractory period distribution (Fig. 7). These bump parameters shape the macroscopic LIC (Juusola and Hardie 2001a, b; Song et al. 2012).

Integration of Light-Induced Current (LIC)

- Input: variable current bumps generated by each microvillus
- Output: macroscopic light-induced current response

Macroscopic LIC of the rhabdomere is integrated from the current bumps of up to 30,000 microvilli (Figs. 2 and 3).

$$LIC = \sum_{N=1}^{N=30,000} I_{in}^N \quad (10)$$

Key assumptions:

- How different microvilli cooperate in producing the LIC is unclear. However, it is assumed that their phototransduction cascades are independent and the macroscopic LIC represents the summation of bumps (Eq. 10). This assumption is valid in dim-to-medium light conditions, where experimentally obtained bump statistics indicate a one-to-one photons-to-bumps relationship (Henderson et al. 2000).

Regulating Bump Waveform and Latency Distribution Statistics Simulations can be made to match to those of recordings by single parameter adjustments. The average bump waveform can be regulated by a single “master” parameter, n_s (Eq. 7), and the average bump latency distribution by another single parameter, la (Eq. 8). n_s and la can be fixed in simulations to produce natural-like bump variations for each light-adaptation state (Figs. 6 and 7). n_s affects mostly the bump shape, whereas la affects mostly the bump latency (Song et al. 2012). Both of these parameters have little effect on the bump refractory period when the bump statistics were within the physiological range for *Drosophila* (Song et al. 2012).

HH Model of Photoreceptor Plasma Membrane

- Input: macroscopic light-induced current response
- Output: macroscopic light-induced voltage response

LICs can be converted to voltage responses by a Hodgkin-Huxley (HH) type of *Drosophila* photoreceptor cell membrane model. This incorporates voltage-gated fast inactivating Shaker and slow delayed rectifier, Shab, K^+ conductances (Hardie 1991; Hardie et al. 1991), and K^+ and Cl^- leaks. It also includes a slowly activating, non-inactivating voltage-gated K^+ conductances and the “window current” representing partial failure of Shaker channel inactivation (−11%). The model lacks further modulation of Shab channels, which are probably located on the microvillar plasma membrane, via phosphoinositide depletion (Krause et al. 2008) and the fast delayed rectifier (Shal current). The conductance for Cl^- leak can be used to regulate the resting potential (Niven et al. 2003; Vähäsöyrinki et al. 2006). The light-dependent conductance is not included, because the phototransduction cascade model provides the functional equivalence to this conductance.

Global Feedback Mechanisms To replicate the effect of slow global feedbacks, such as

intracellular accumulation or diffusion of Ca^{2+} , a global feedback strength parameter can be implemented in the phototransduction cascade model (n_s in Eq. 7). In the simplest case, by changing n_s exponentially (Eq. 11), the model reproduces the slow light-adaptation trends (exponential decay to plateau) in the LIC responses to light pulses (Fig. 5):

$$n_s = n_{s0} + A_{n_s} - A_{n_s} \exp(-t/\tau_{n_s}) \quad (11)$$

where n_{s0} denotes the initial condition for n_s , $n_{s0} + A_{n_s}$ is the value for n_s at, $t \rightarrow \infty$ and τ_{n_s} is the time constant of n_s dynamics. These parameters for n_s at different light levels can be found in Song et al. (2012).

Owing to the model structure, the voltage regulation of the TRP/TRPL channels' driving force can be implemented as a global feedback mechanism. This procedure reveals the interplay between the light-sensitive and light-insensitive membrane, when the photoreceptor is encoding vast changes in light intensity.

Specifically, I_{in} , formulation from Eqs. 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11 and 12 can be modified:

$$I_{in}^N = (T^*N)(g_{TRP})(TRP_{rev} - V_m) \quad (12)$$

where T^*N is the number of opened TRP/TRPL channels in the N th microvillus, g_{TRP} is the single TRP channel conductance, TRP_{rev} is TRP channel reversal potential, and V_m is the membrane voltage. g_{TRP} can be formulated according to Eq. 13:

$$g_{TRP} = 8 \times \begin{cases} 1 & \text{if } TRP_{rev} > V_m \\ 0 & \text{otherwise} \end{cases} \quad (13)$$

In this way, TRP/TRPL channels are either fully closed or fully opened, with a single-channel conductance of 8 pS in the open state. TRP_{rev} is set to 0 mV (Hardie and Postma 2008).

From Eq. 12, as membrane voltage (V_m) increases, the bumps (I_{in}^N) shrinks accordingly, reducing the overall macroscopic LIC response

(Eq. 10). Since the phototransduction cascades and the membrane are modeled separately in two compartments, the cell membrane voltage (V_m) is obtained by injecting LIC into the Hodgkin-Huxley-type cell body model

$$V_m = HH(LIC) \quad (14)$$

where HH is a function representing the cell membrane model.

The iteration process is conducted between these two model compartments (Eqs. 10, 11, 12, and 13) to obtain realistic macroscopic LIC s and voltage responses. Thus, the calculation of I_{in}^N in Eq. 12 requires membrane potential feedback, V_m , which is initialized at the resting potential (-70 mV). As a result, I_{in}^N in every microvillus is larger than the true value, and hence LIC_0 obtained in Eq. 10 is larger than the true value of LIC . Accordingly, LIC_0 charges a too large voltage response V_{m1} . To obtain a more realistic LIC , V_{m1} is fed back to Eq. 12; but as a result, LIC_1 can be smaller than the true value (i.e., the obtained values oscillate). Hence, an iterative simulation procedure between rhabdomere and the cell body is conducted to acquire the converged LIC and V_m . Here, it is assumed that the voltage feedback only affects the amount of current influx through the opened TRP/TRPL channels but not the dynamics of the phototransduction; T^*N is not changing in each microvillus.

Definition

Physical sectioning microscopy is a technique for three-dimensional (3D) imaging of large biological tissue volumes. As the name suggests, the technique involves physically cutting or ablating tissue to expose successively deeper parts of the tissue volume while imaging the freshly exposed tissue. The approach is in contrast with optical sectioning (e.g., confocal or multiphoton imaging), where volume imaging is performed on small intact tissue volumes, by means of systematically varying the focal plane. The main advantage of physical sectioning over optical sectioning is that it is able to image larger volumes without deterioration in the signal-to-noise ratio, and thus it is ideal for imaging whole organs such as the brain. Another important advantage of physical sectioning is that the axial resolution (in the depth direction) can be at least an order of magnitude higher than optical sectioning.

Detailed Description

The recent surge of interest in quantitative investigation of the brain as a whole has led to a rapid technological development in 3D volume imaging methods. Existing 3D imaging methods that depend on optical sectioning such as confocal microscopy or multiphoton microscopy were deemed inadequate to address the depth and volume requirements posed by whole brain imaging

(latest methods such as light sheet microscopy may be able to overcome some of these limitations). Noninvasive imaging methods based on magnetic resonance (MR) or X-ray were not up to the task, since they either lacked the means to label neurons or offered insufficient spatial resolution, or both.

For large volume brain imaging, physical sectioning (or serial sectioning) is an obvious alternative to optical sectioning or MRI/X-ray (see, e.g., the BigBrain project where a whole human brain was cut into 20µm thin sections and imaged; Amunts et al. 2013). In fact, physical sectioning has been used successfully in the past; however,

Physical Sectioning Microscopy, Table 1 Comparison of representative physical sectioning microscopy techniques

	Sectioning	Post-sectioning preparation	Time of imaging (imaged part)	Imaging modalities	Limiting factors	References
Array tomography	Microtome (linear)	Pasted on glass slides	Post-sectioning (slide). Repeated staining/imaging possible	Fluorescence, SEM	Diffraction limited (fluorescence), imaging slow (fluorescence), imaging very slow (SEM), volume (manual steps)	Micheva and Smith (2007)
KESM	Microtome (linear)	None	During sectioning (slice, at the knife's edge)	LM	Diffraction limited	Mayerich et al. (2008); Choe et al. (2008); Chung et al. (2011) (cf. Li et al. 2010)
SBF-SEM	Microtome (linear)	None	Immediately after sectioning (block face)	SEM	Volume, imaging very slow	Denk and Horstmann (2004)
ATLUM	Microtome (lathe)	Pasted on a spool of carbon-coated tape and later transferred to wafer	After transferring to the wafer (slice)	TEM	Imaging very slow	Hayworth et al. (2006)
Serial two-photon tomography	Microtome (linear)	None	Immediately after sectioning (block face)	Fluorescence	Diffraction limited, imaging slow	Ragan et al. (2012)
3D polarized light microscopy	Microtome (linear)	Pasted on glass slides	Post-sectioning (slide)	Polarized light	Resolution of around 100 µm × 100 µm	Axer et al. (2011)
All optical histology	Femto second laser	None	Immediately after ablation (block face)	Fluorescence	Diffraction limited, imaging slow	Tsai et al. (2003)
FIB-SEM	Focused Ion beam	None	Immediately after ablation (block face)	SEM	Volume, sectioning very slow. Imaging very slow	Hayles et al. (2007)

Abbreviations: *SEM* scanning electron microscopy, *LM* light microscopy, *TEM* transmission electron microscopy

the sectioning and imaging process was largely manual, and thus it required a tremendous amount of effort just to process small amounts of tissue (see, e.g., White et al. 1986). Here, we will discuss automated approaches for physical sectioning imaging.

Means of Physical Sectioning

Currently there are two major means of physical sectioning used in 3D microscopy: One is the use of microtomes (knives typically made of diamond), and the other is the use of focused ion beams (FIB) or femtosecond lasers. Both are equally effective, but depending on the imaging modality one or the other may be more suitable. Microtomes can be used to generate ultrathin sections that can be immediately imaged or preserved for subsequent imaging, while FIB or femtosecond lasers can only be used for immediate block-face imaging since the affected top layer of the tissue will be destroyed by the milling process. The sectioning or milling thickness typically ranges from tens of nanometers to hundreds of nanometers.

A Brief Survey of Physical Sectioning Microscopy Techniques

Physical sectioning has been successfully used with different imaging modalities, such as light and fluorescence microscopy and even with electron microscopy. Here, we discuss representative examples only and defer more detailed discussions to existing reviews (see, e.g., Choe et al. 2008; Chung et al. 2011; Wilt et al. 2009).

Representative techniques that use microtome-based serial sectioning include array tomography (Micheva and Smith 2007), knife-edge scanning microscopy (KESM, Mayerich et al. 2008), serial block-face scanning electron microscopy (SBF-SEM, Denk and Horstmann 2004), Automatic Tape-Collecting Lathe Ultramicrotome (ATLUM, Hayworth et al. 2006), serial two-photon tomography (Ragan et al. 2012), and 3D

polarized light microscopy (3D-PLI, Axer et al. 2011). Representative approaches using lasers or ion beams for ablation include All Optical Histology (Tsai et al. 2003) and Focused Ion Beam Scanning Electron Microscopy (FIB-SEM, Hayles et al. 2006). Note that Serial Two-Photon Tomography and All Optical Histology are hybrid approaches that combine physical sectioning and optical sectioning.

Table 1 below summarizes the characteristics and capabilities of the representative approaches listed above. Note that each approach has limiting factors, so no single approach is sufficient.

In summary, physical sectioning microscopy enables high-resolution 3D imaging of large volumes of biological tissue, allowing multi-scale quantitative investigation of the anatomical properties of whole organs such as the brain.

Physiology and Computational Principles of Muscle Force Generation

George A. Tsianos and Gerald E. Loeb
Department of Biomedical Engineering,
University of Southern California, Los Angeles,
CA, USA

Definition

Muscle force generation refers to the process in which skeletal muscle, in response to neural stimuli, converts metabolic energy into active force that pulls on the bones through intermediate connective tissue.

Detailed Description

Introduction

The control problems that must be solved by the sensorimotor nervous system are determined by the complex mechanical properties of the musculoskeletal system and the even more complex and nonlinear physiological properties of muscles. Various commercial software products have been available to model musculoskeletal mechanics, but realistic models of muscle physiology are still under development. Both force generation and energy expenditure depend on both the commands from the nervous system and the kinematics of muscle length and velocity. Computational models of these processes provide the substrate upon which computational models of sensorimotor control must operate to demonstrate their feasibility.

Computational models are always approximations and usually simplifications of reality. It is usually both necessary and desirable to leave out known complexities if they do not significantly impact the particular behavior to which the model will be applied. The model presented here includes the most accurate representations currently available for the force-generating processes of individual motor units. Most previous and current research has used models that are considerably simpler, sometimes with clear justification but often from lack of consideration of relevant processes, parameters, and effects. The computational model presented here is embedded in free-ware for modeling complete, arbitrary musculoskeletal systems, including their mechanical dynamics, muscles and proprioceptors, and interactions with external objects (MSMS – MusculoSkeletal Modeling Software – available from <http://mddf.usc.edu>). The construction of a particular model configuration and specification of its parameters, however, must come from the researcher after due consideration of the purposes of the model.

Relevant Physiology

Each muscle is controlled by a group of motoneurons known as a motor pool or motor nucleus. All motoneurons in such a pool generally receive the

same drive signals, although there are some exceptions (Loeb and Richmond 1989). Each motoneuron along with all of its muscle fibers is defined as a motor unit, whose recruitment and firing rate in response to the same drive varies substantially depending on the size and impedance of the motoneuron (Henneman and Mendell 1981). The force generated by a given motor unit at a given rate of firing depends on the total cross-sectional area of the muscle fibers in the unit.

The force production and corresponding energy consumption of each motor unit depend mainly on its length, velocity, and firing rate. Because muscle fibers within a motor unit generally have the same contractile properties, they can be lumped into one mathematical entity whose force generating capacity is proportional to the total cross-sectional area of its fibers and whose energy consumption is proportional to their volume. All of the muscle fibers in all of the motor units of a given muscle tend to move together, experiencing the same sarcomere lengths and velocities. Because of this homogeneity, most of the experimental phenomena related to contraction of whole muscle can be explained by processes occurring at the sarcomere level.

The sarcomere is the basic unit of the contraction apparatus. It is demarcated at its ends by thin Z-plates from which a matrix of thin filaments of actin projects in each direction. These interdigitate with a matrix of thick filaments of myosin that are held in the center of the sarcomere by strands of the highly elastic connectin filaments that tether the thick filaments to the Z-plates. In order for muscles to contract, protrusions from myosin called myosin heads must first be cocked to a relatively high-strain configuration and then attached to neighboring binding sites on the actin. The resulting crossbridges act like springs that pull on the actin. The metabolic energy required to cock the myosin head is provided directly by ATP molecules that are present in the sarcoplasm. In order for myosin heads to attach to neighboring binding sites, a regulatory protein called tropomyosin that normally occludes actin binding sites must undergo a conformational change. This occurs indirectly through binding of calcium to troponin, a relatively smaller

molecule that is bound to tropomyosin at regular intervals along its length. When calcium binds to troponin, a local conformational change is induced that exposes nearby actin binding sites so that the cocked myosin heads can attach to form crossbridges.

The normally relaxed state of inactive muscle is achieved by ATP-powered pumping of the calcium out of the sarcoplasm and into a network of vesicles called longitudinal tubules, preventing crossbridge formation. When the muscle is activated, calcium is released from cisterns in these longitudinal tubules in response to action potentials elicited in the muscle fibers as a result of a chemical synapse with the motor axons. These action potentials propagate along the cell membrane and its invaginations deep into the muscle fiber called transverse tubules. The ATP molecules that cock the myosin heads and drive the ion pumps must be replenished eventually via catabolism of glucose occurring both in the sarcoplasm (glycolytic) and within mitochondria (oxidative), consuming additional energy. The model of muscle presented here attempts to represent each of these structures and processes as explicit terms in the set of equations that comprise the model. A model of the energetics based on these processes can be found in Tsianos et al. (2012) and is embedded in MSMS (see above).

Structure of the Model

The model is an assembly of sub-models, each characterizing a major physiological process underlying muscle contraction (Fig. 1). Modeling physiological processes independently as opposed to the aggregate behavior avoids overfitting data to specific preparations and therefore improves the likelihood that the model will be valid under untested conditions. The data driving the model originate from experiments on mammalian muscle that were designed to isolate specific processes that were then quantified. These include a wide variety of preparations with various muscle fiber architectures, but the model parameters have been normalized to dimensionless variables that depend on the constant structures of the sarcomeres, which are highly similar across all mammalian skeletal muscles.

Physiology and Computational Principles of Muscle Force Generation, Fig. 1 Model overview. Independently modeled physiological processes and their

contribution to muscle force production and energy consumption. (Figure from Tsianos et al. 2012, Fig. 11)

P

The physiological properties of muscle can change over time. In the short term, force generation may increase or decrease as a result of chemical changes associated with potentiation and fatigue, respectively. In the longer term, muscle morphology and physiology may change as a result of trophic responses to patterns of use such as exercise and injury. All of these effects tend to be specific to the various muscle fiber types, making it important to develop muscle models that reflect the subpopulations of fiber types and the relative recruitment of the motoneurons that control them. The one-to-one correspondence of the model's terms and coefficients to physiological processes makes it relatively straightforward to extend it to include unaccounted aspects of muscle contraction and

to adjust its coefficients to model changes over time. Unfortunately, quantitative models of most of these time-varying processes have yet to be developed or validated.

Active Force

Frequency Recruitment As the net excitatory synaptic drive increases to a pool of motoneurons, they tend to be recruited in a fixed order from those innervating slow-twitch muscle fibers to those innervating fast-twitch muscle fibers. Increasing the drive past the threshold of a given motoneuron results in higher firing rates. This monotonic relationship can be approximated by a line whose slope depends on the recruitment threshold of the motor unit (see Fig. 2).

Physiology and Computational Principles of Muscle Force Generation, Fig. 2

Motor unit recruitment and modulation. The plot emphasizes the relatively higher recruitment threshold of larger motor units (e.g., *fast* vs. *slow twitch*) and their firing rate modulation until the common drive (U) saturates the firing rate of all motor units. (Figure from Cheng et al. 2000, Fig. 2)

$$f_{env_i} = f_{min} + \left(\frac{1 - U_{MU_i}^{th}}{f_{max} - f_{min}} \right) * U$$

Note that the firing rate is normalized to $f_{0.5}$ (frequency at which the motor unit produces half of its maximal isometric force) because motor units tend to fire between $1/2f_{0.5}$ and $2f_{0.5}$, the range over which muscle activation is most steeply modulated.

Calcium Kinetics and Crossbridge Activation

(f_{eff} , A_f) The sigmoidal relationship between motoneuron firing rate and activation of the contractile apparatus arises from the release, diffusion, and reuptake of calcium (see Fig. 3). At low pulse rates, the calcium released by each pulse is completely cleared before the next pulse, resulting in small, discrete twitches. As pulse rate increases, the calcium released by each pulse starts to accumulate to higher concentrations, allowing the calcium to diffuse further and expose more crossbridge binding sites. Eventually, the calcium concentration in all parts of the muscle fiber becomes sufficient to expose all binding sites and activation plateaus even if firing rate continues to increase. This is called a tetanic contraction.

The equation below captures the effects of firing rate on crossbridge activation. Y corresponds to yielding behavior exhibited by slow-twitch fibers and Sag observed in fast-twitch fibers. Both phenomena affect crossbridge activation through hypothesized mechanisms discussed in the corresponding sections. Note that equation parameter n_f is length dependent. The shape of the sigmoid relationship is defined by a_f , n_{f0} , and n_{f1} constants, some of which are fiber-type dependent. For a complete definition of all model parameters, see Tsianos et al. (2012).

$$A_f(f_{eff}, L_{ce}, V_{ce}) = 1 - \exp \left[- \left(\frac{Y S f_{eff}}{a_f n_f} \right)^{n_f} \right] n_f$$

$$= n_{f0} + n_{f1} \left(\frac{1}{L_{ce}} - 1 \right)$$

Sag (S) When fast-twitch muscle is excited isometrically with a constant drive, its force output increases initially to some maximal level and then decreases gradually (Fig. 4). This is thought to occur due to an increase in the rate of calcium reuptake, which effectively reduces the concentration of calcium in the sarcoplasm and hence the number of crossbridges that can form.

Physiology and Computational Principles of Muscle Force Generation, Fig. 3 Calcium kinetics and crossbridge activation. The effects of firing rate on isometric force output of muscle are shown from zero to tetanic activation. Overlaid graphics highlight underlying processes at the sarcomere level that give rise to the behavior. Only a small portion of the sarcomere is shown here due to symmetry. Thick horizontal bars represent thick filaments and thin horizontal lines represent thin filaments. Vertical

bars correspond to Z-disks. The small red spheres are calcium ions whose bond with actin sites is indicated by short black lines that link them and a small red dot overlaid on top of the actin (gray dots indicate inactive binding sites). If a crossbridge is formed, then the small ovals in the figure representing myosin heads are colored blue and are in a cocked configuration (large angle with respect to their neck region). (Figure from Tsianos and Loeb, Muscle Physiology and Modeling, article in Scholarpedia, Fig. 3)

Physiology and Computational Principles of Muscle Force Generation, Fig. 4 Sag. Experimental data depicting the Sag phenomenon in response to constant stimulation for several frequencies. The graphics on the bottom portion illustrate the effect of increasing the rate of calcium reuptake on calcium concentration and crossbridge formation (Top plot from Brown and Loeb 2000, Fig. 3a. Bottom schematic from Tsianos and Loeb, Muscle Physiology and Modeling, article in Scholarpedia, Fig. 4)

Physiology and Computational Principles of Muscle Force Generation, Fig. 5 Force-length relationship. Muscle force dependence on length is shown for tetanically stimulated muscle with minimal motion of its myofilaments. Overlaid graphics depict myofilament overlap and effects on crossbridge formation for different lengths.

This phenomenon can be modeled by a time-varying scaling factor applied to f_{eff} , which is directly related to the calcium present in the sarcoplasm (Brown and Loeb 2000).

$$S(t, f_{\text{eff}}) = \frac{a_s - S(t)}{T_s}$$

Force-Length (FL) The amount of active force a muscle produces during maximal isometric contractions (i.e., muscle length held constant during the contraction) depends on the length at which it is fixed (Fig. 5). It produces large forces at intermediate lengths and relatively smaller forces at either shorter or longer lengths (Scott et al. 1996).

At some intermediate length, typically referred to as optimal length, overlap between thin filaments and myosin heads is maximal. Therefore, the number of crossbridges that could form and the contractile force are also maximal. Myofilament overlap is less at longer lengths, so the number of potential

crossbridges and force is also smaller. Muscle force decreases at incrementally longer lengths until the point at which no more crossbridges can form and muscle can no longer produce active force. At relatively shorter lengths, thin filaments start to slide past each other (i.e., double overlap), which is thought to sterically hinder the formation of crossbridges, thereby reducing the amount of force that can be produced.

The force-length relationship, as well as all other relationships in the model, is normalized so that it generalizes across a wide range of muscle morphometries. The force corresponding to optimal length is by definition maximal, so, clearly, normalizing all force profiles to maximal isometric force under tetanic conditions provides a useful reference point. The equation capturing the normalized relationship is shown below.

$$FL(L_{ce}) = \exp\left(-\left|\frac{L_{ce}^\beta - 1}{\omega}\right|^\rho\right)$$

Physiology and Computational Principles of Muscle Force Generation, Fig. 6 Force-velocity relationship. Dependence on muscle force output on the velocity of stretch ($V > 0$) and shortening ($V < 0$) for tetanic stimulation at optimal muscle length. The graphics illustrate the hypothesized mechanisms for force enhancement relative to isometric in the lengthening case and depression in the

shortening case. Note that in reality myosin heads do not move synchronously as shown in the figure because they are subject to thermodynamic noise and other stochastic events; the graphic illustrates their configuration on average. (Figure from Tsianos and Loeb, *Muscle Physiology and Modeling*, article in Scholarpedia, Fig. 6)

ω , β , and ρ are constants that define the exact shape of the inverted U and are all fiber-type dependent.

Force-Velocity (FV) Maximally stimulated muscle at a particular length produces different levels of force depending on the rate at which it is shortening or lengthening. Relative to the isometric condition, muscle produces less force while shortening and more force while lengthening (Fig. 6; Scott et al. 1996).

Shortening muscle is accompanied by motion of the attached crossbridges toward relatively less

strained configurations. Larger rates of shortening increase the probability that a given crossbridge will be in a low-strain configuration; therefore, the force generated by the entire population is lower overall. By contrast, crossbridges in lengthening muscle become relatively more stretched and generate more tension until they are forcibly ripped away from the actin binding sites.

The equations below account for the discontinuous effects of the two, separate mechanisms by which velocity affects force generation:

$$FV(V_{ce}, L_{ce}) = \begin{cases} (V_{\max} - V_{ce}) = V_{\max} + (c_{v0} + c_{v1}L_{ce})V_{ce}, & V_{ce} \leq 0 \\ b_v - (a_{v0} + a_{v1}L_{ce} + a_{v2}L_{ce}^2)V_{ce}/(b_v + V_{ce}), & V_{ce} > 0 \end{cases}$$

c_{v0} , c_{v1} , and $V_{\max}$ are constants that define the shortening end of the relationship and depend on fiber type. $V_{\max}$ corresponds to the maximum

velocity of shortening that the muscle fiber can undergo. The lengthening portion of the relationship is defined by fiber-type-dependent constants

b_v , a_{v0} , a_{v1} , and a_{v2} . Note that the force-velocity relationship also depends on muscle length. See “**Potentialiation**” for a detailed description of this phenomenon as well as a mechanistic explanation. **Interactions Among Length, Velocity, and Activation**

Length Dependency of Calcium Kinetics - Changing length of the sarcomeres has effects on the calcium kinetics that govern activation. The cisterns from which the calcium is released appear to be tethered to the Z-plates at a location that is near the middle of the actin-myosin overlap when the muscle is at optimal length. At longer lengths, calcium has to diffuse over longer distances to get to the actin binding sites, which takes more time. Thus the rise times of the activation are longer (see Brown et al. 1999; Brown and Loeb 2000).

Length Dependency of Crossbridge Dynamics - Changing length of the sarcomeres has effects on the rate of attachment of crossbridges to activated and exposed binding sites on the actin. Because a

muscle fiber does not gain or lose volume as it changes length, the fiber must have a larger diameter when it is at a shorter length. The hexagonally packed lattice of myofilaments in each sarcomere will then be more widely spaced, changing the distance between the myosin heads and the thin filaments where they must bind to form crossbridges. The heads are located on the ends of hinged arms containing myosin light chains, which are canted away from the longitudinal axis of the thick filament. When the sarcomere is at a long length, the myosin heads barely fit between the thick and thin filaments, so they are close to and can bind rapidly to form crossbridges. At short lengths, the myosin heads are less favorably disposed and their binding may also be affected adversely by the double overlap of the thin filaments. These effects are particularly large at lower levels of activation, where activated binding sites are more scarce on the thin filaments. The net result is shown in Fig. 7, which is based on data and models first described in Brown et al. (1999).

Physiology and Computational Principles of Muscle Force Generation, Fig. 7 Length dependence of crossbridge activation. Crossbridge activation is measured as the percentage of maximal force generated for a given amount of myofilament overlap (i.e., effects of myofilament overlap are removed from muscle force). Muscle

length is fixed at three different values. In general, a larger portion of the available contractile machinery is activated for the same firing rate when the muscle is stretched. The *middle curve* corresponds to optimal length. (Figure from Tsianos and Loeb, Muscle Physiology and Modeling, article in Scholarpedia, Fig. 7)

The precise slope of this relationship, i.e., the sensitivity of force to firing rate, is affected by additional factors. A low firing rate activates only a small portion of the binding sites on the actin filaments. An incremental increase in the firing rate results in a relatively larger increase in the number of crossbridges formed. This is probably due to a relatively larger amount of exposed binding sites per active troponin molecule; this mechanism is known as cooperativity (Gordon et al. 2000; Loeb et al. 2002). Activation of troponin induces a local conformational change in tropomyosin, exposing neighboring binding sites on the actin. When more troponin molecules are activated along tropomyosin, a more global conformational change could be occurring, thus freeing up more actin binding sites. Crossbridge formation may also facilitate exposure of binding sites by inducing relative motion between actin and tropomyosin.

Potentialiation

It was originally observed that the force generated by a single twitch of a fast-twitch muscle was much larger after a brief tetanic contraction than before. In fact, the potentiated state tends to prevail for minutes after a few, brief trains of stimulation at physiological rates, suggesting that the normal operating state of fast-twitch muscle is the potentiated state and that the conditions observed after a long period of quiescence reflect a dispotentiated state (see Brown and Loeb 1998). Furthermore, the dispotentiated state exhibits rather odd behavior such as a pronounced rightward shift in the shape of the force-length curve at subtetanic frequencies. For these reasons, the model of the fast-twitch muscle fibers presented here captures their behavior in the fully potentiated state.

Potentiation and dispotentiation phenomena appear to be related mainly to the effects of myofilament lattice spacing described above, but see also Smith et al. (2013). During dispotentiation, the light chain becomes dephosphorylated and the cant angle becomes smaller, leaving the myosin heads further from the thin filaments. The effect is greater at short lengths when the lattice spacing is large. This adversely affects the kinetics of crossbridge formation in general but more so at low firing rates when exposed binding sites are more sparsely distributed.

After a few cycles of calcium release in an active muscle, the short chains become fully phosphorylated and the cant angle increases so as to position the myosin heads more favorably at short and optimal muscle lengths. At longer lengths and narrower lattice spacings, the myosin heads probably remain favorably positioned because they cannot get by the closely spaced thin filaments. The force-length relationship thus returns to the simple inverted U with maximum at optimal myofilament overlap regardless of the firing rate. Slow-twitch muscle appears to lack such a dephosphorylation process and so behaves always as if fully potentiated. The function of the dispotentiation remains obscure but may be related to minimizing “stiction,” which arises when stray crossbridges in an inactive muscle form spontaneously and resist passive stretching by antagonist muscles.

The effects of sarcomere length on myofilament lattice spacing give rise to length dependencies of the force-velocity relationship that are different for slow- and fast-twitch muscle (Fig. 8). For slow-twitch muscle, the force-velocity relationship depends on length only for the lengthening condition, while fast-twitch muscle exhibits a dependency for the shortening condition. In lengthening slow-twitch muscle, smaller spacing between myosin heads and binding sites would result in a higher probability of crossbridge formation, thus leading to higher forces produced for the same velocity of stretch. This effect is also observed in dispotentiated fast-twitch muscle, but not in the potentiated state, because the reduction of interfilament spacing resulting from potentiation is thought to mask the effects of length changes (Brown and Loeb 1999). In shortening fast-twitch muscle, it is thought that smaller interfilament spacing at longer lengths increases the probability that a given crossbridge remains attached, thus making it more likely that it occupies relatively low-strain, low force configurations. Crossbridges in slow-twitch muscle stay attached for longer periods of time, which may mask the effects of length on the rate of detachment hypothesized for fast-twitch muscle.

Yield (Y) When slow-twitch muscle is sub-maximally stimulated at constant length and then

Physiology and Computational Principles of Muscle Force Generation, Fig. 8 Length dependence of force-velocity. Force-velocity curves depicting a substantial length dependency of slow-twitch muscle in the

lengthening state (*left*) and fast-twitch muscle in the shortening state (*right*). See text for details. (Figure from Tsianos and Loeb, *Muscle Physiology and Modeling*, article in Scholarpedia, Fig. 8)

stretched *or* shortened, its force output declines (Joyce et al. 1969). This effect intensifies for lower stimulation frequencies, as shown in Fig. 9. The mechanism for this phenomenon has been hypothesized to be a reduction in the number of crossbridges attached. As muscle length changes past the stroke length of the attached crossbridges, myosin heads detach from their binding sites and must reattach to continue to produce force. The rate at which slow-twitch myosin heads can attach appears to be relatively slow compared to the rate at which binding sites slide past them, therefore making it difficult for crossbridges to reform and produce force. At lower frequencies of stimulation, relatively few binding sites are available on the helical actin, making it less likely that they will be in an appropriate orientation and distance from myosin heads for binding. By applying a time-varying scaling factor to the effective firing rate parameter, the model is able to capture this effect well (Fig. 9).

$$Y(t) = \frac{1 - c_Y \left[1 - \exp \left(-\frac{|V_Z|}{V_Y} \right) \right] - Y(t)}{T_Y}$$

c_Y and V_Y are constants that define the intensity of the yielding effect and T_Y defines its time course.

Passive Elastic Elements

Muscle is comprised of many elastic components that generate passive forces in response to tensile or compressive strain. The aggregate force of these components may be substantial relative to the active force depending on the muscle's condition of use.

Parallel Elastic Element (F_{pe1}) Inactive muscle is under tension for about half of its anatomical range of lengths. Its passive tensile force rises exponentially over a relatively low range of lengths followed by a steep linear increase that persists all the way until maximal anatomical length (Fig. 10). The quantitative relationship for a particular muscle depends mainly on its maximal isometric force and maximal anatomical length. It is negligible over most of the range and peaks at less than 10% of F_0 at maximal anatomical length.

In frogs, this passive tension appears to arise primarily from stretching of the springlike connectin myofilaments that tether the myosin molecules to the Z-disks (Magid and Law 1985). The contribution of intermediate filaments like desmin that interconnect myofibrils within a muscle fiber has been shown to be negligible over the physiological range of sarcomere lengths (Wang

Physiology and Computational Principles of Muscle Force Generation, Fig. 9 Yielding. Plot of force-velocity relationships of slow-twitch muscle for various frequencies of stimulation. As opposed to tetanic stimulation, the force-velocity relationships for submaximal firing

rates are marked by a sharper decline in force in both shortening and lengthening states relative to isometric. Experimental data and model predictions, with and without accounting for yielding, are shown. (Figure from Brown et al. 1999, Fig. 10b)

Physiology and Computational Principles of Muscle Force Generation, Fig. 10 Parallel elastic force. Passive muscle force is plotted over a representative muscle's range of motion. In general, muscles with larger anatomical ranges of motion produce less passive force at the same length (relative to optimal), that is, their passive force-length curve shifts to the right. As depicted by the

superimposed schematics, some of this force results from stretching an elastic element in the sarcomere called connectin that links the thick filament to the Z-disks, but see text for the role of endomysial connective tissue. Myosin heads and actin binding sites are omitted for clarity. (Figure from Tsianos and Loeb, Muscle Physiology and Modeling, article in Scholarpedia, Fig. 10)

et al. 1993). Compared to frogs, mammalian muscles have variable but considerably more endomysial collagen surrounding each muscle fiber.

This may account for substantial variation in their passive force curves, which can be substantially shifted to the left or right with respect to the

optimal sarcomere length defined by myofilament overlap (Brown et al. 1996a). This requires introduction of an additional morphometric parameter into the muscle model, $L_{\max}$, which is based on the maximal anatomical length experienced by the muscle when attached to the skeleton. Below is the equation capturing the effect of this property on the entire passive force-length relationship.

$$F_{pe1}(L_{ce}, V_{ce}) = c_1 k_1 \ln \left\{ \exp \left[\frac{L_{ce}/L_{ce}^{\max} - L_{r1}}{k_1} \right] + 1 \right\} + \eta V_{ce}$$

c_1 , k_1 , and L_{r1} are constants defining the precise shape of the curve. Linear damping was also incorporated into the equation with constant coefficient, η , to account for the small amount of damping observed experimentally, which also contributes to the mathematical stability of the model.

Thick Filament Compression (F_{pe2}) At very short lengths, muscles generate passive force that opposes the force of contraction. This force is negligible for long lengths but starts to increase exponentially from $0.7 L_0$ until the minimum physiological length where net contractile force goes to zero (see Fig. 11; Brown et al. 1996b).

The steady-state force produced by tetanically stimulated muscle decreases at a fairly constant

rate for the range of lengths from L_0 to $0.7L_0$, reflecting steric interference between the overlapped thin filaments. At this relatively small length, however, the slope steepens abruptly and remains steep until the length at which net muscle force is zero. Assuming that the effects of double overlap on crossbridge formation are the same over the entire range of lengths in which it occurs, the number of crossbridges, hence force, should decrease proportionally with decreasing length. The abrupt change in force appears to reflect a collision between the myosin filament and the Z-disk, which would generate a reaction force opposing the force of contraction. The extent of compression of the myosin filament onto the Z-disk would be less for submaximal contractions because the number of crossbridges generating force would be relatively smaller. Thus it is important to model this effect separately from the force-length relationship, which affects force generation equally at all activation levels. The equation below computes the force at the muscle level as a function of length that opposes the force of contraction.

$$F_{pe2}(L_{ce}) = c_2 \{ \exp [k_2(L_{ce} - L_{r2})] - 1 \}$$

Constants c_2 , k_2 , and L_{r2} define the exact shape of the relationship depicted in Fig. 11.

Physiology and Computational Principles of Muscle Force Generation, Fig. 11 Thick filament compression. Plot shows the parallel passive force of muscle opposing the contractile force as a function of fascicle length. The schematics illustrate the hypothesis that this force arises due to compression of the thick filament as the Z-disks are pulled even closer together at short muscle lengths. (Figure from Tsianos and Loeb, Muscle Physiology and Modeling, article in Scholarpedia, Fig. 11)

Series Elastic Element (Tendon + Aponeurosis; F_{se}) Muscles exert forces on bone segments through intermediate connective tissue, comprised mostly of aponeurosis and tendon. This serially connected tissue affects the muscle's motion, which modulates force output substantially. Clearly, the length of a muscle for a particular joint configuration depends on the length of the series elastic element because together they must span the entire path from the origin to the insertion site of the musculotendon. The portion of the path that is occupied by muscle depends not only on the resting length of the series elastic element but also on its elasticity, which determines how much it will stretch when it is pulled by the attached muscle. If a muscle is activated and then deactivated under isometric conditions as defined at the origin and insertion, the sarcomeres may experience large changes in length and especially velocity that will affect their force-generating ability. Note that the series elastic element is a nonlinear spring (see below and Fig. 12),

which undergoes a substantial portion of its ultimate strain at relatively low stresses, i.e., at low levels of muscle recruitment. Under dynamic conditions of activation and kinematics, the muscle fibers may actually move out of phase with the musculotendon (Zajac et al. 1981). This has important implications for the ability of muscle spindles to encode musculotendon length, hence joint position (Hoffer et al. 1992; Scott and Loeb 1994; Mileusnic et al. 2006).

The magnitude of the effects described above depends on the ratio of the lengths of the muscle fascicles to the connective tissue in series with them. Highly pinnate muscles have short muscle fibers oriented obliquely between fascial planes called aponeuroses that merge with the external tendon. Proximally, the aponeurosis has a thin sheetlike structure with a large surface area to accommodate insertion of a large number of fibers while more distally its shape gradually becomes thicker and smaller in surface area. It has been shown experimentally that for a wide range of

Physiology and Computational Principles of Muscle Force Generation, Fig. 12 Series elastic tendon/aponeurosis force. Force generated by elastic tissue that is in series with muscle as a function of its length. The schematic shows that for a given musculotendon length and low muscle activation (*bottom*), the tendon will be relatively slack and therefore produce little restoring force. At higher

activation levels (*top*), the muscle pulls more on the tendon and causes a larger restoring force. The stiffness is also greater in this case, denoted by the increased slope of the relationship, because the tendon becomes tauter at these higher force levels. (Figure from Tsianos and Loeb, Muscle Physiology and Modeling, article in Scholarpedia, Fig. 12)

muscle forces, aponeurosis and tendon strain are the same (Scott and Loeb 1995). The fact that the gradual thickening of the aponeurosis is paralleled by an increase in the number of fibers that exert force on it suggests that the stresses are fairly constant along its entire length. Because the stress and strain experienced by the aponeurosis and tendon are roughly the same, then presumably their material properties are similar and they can be lumped into a single element. The absolute thickness and strength of this connective tissue element is presumably controlled by trophic factors that depend on the maximal tensile forces that it experiences. The model assumes that tendon force scales with muscle cross-sectional area, or equivalently it scales with F_0 , and strain is measured with respect to tendon length at F_0 (L_0^T), permitting a generic relationship to be derived (see Fig. 12). This has been confirmed using several force-length relationships of the tendon/aponeurosis obtained experimentally (Brown et al. 1996b). L_0^T is a good normalization factor because it can be determined more reliably as opposed to the more commonly used tendon slack length. The equation that defines this relationship is shown below.

$$F_{se}(L_{se}) = c^T k^T \ln \left\{ \exp \left[\frac{L_{se} - L_r^T}{k^T} \right] + 1 \right\}$$

Constants c^T , k^T , and L_r^T define the precise form of the relationship shown in Fig. 12.

Parameters Needed to Model Specific Muscles

Musculotendons are comprised of the same basic elements, such as sarcomeres for contractile elements and collagen for passive elements, whose structural organization and properties lead to substantially different behavior on the whole musculotendon level. Knowledge of musculotendon morphometry and fiber-type-specific properties of sarcomeres is crucial for tailoring the generic relationships that comprise the model to the specific muscle of interest. The general physiological models above all employ normalization to dimensionless parameters (Topp et al. 1986) and so must be converted into real physical units (e.g., cm, N) by morphometric

parameters of the musculoskeletal system to be modeled.

Optimal Fascicle Length (L_0)

As mentioned in “Relevant Physiology,” sarcomeres have roughly the same dimensions and experience the same range of length changes during a contraction. Longer muscle, therefore, has more sarcomeres in series. This means that a given change in muscle length of a longer muscle is accompanied by relatively smaller length changes at the sarcomere level, hence a smaller change in myofilament overlap and force produced. Because the dimensionless force-length relationship applies to behavior at the sarcomere level, it must be scaled by the length of the muscle to account for this architectural effect on the behavior of the whole muscle. The morphometric parameter used for this purpose is optimal fascicle length, which is the distance between the aponeurosis sites measured along the orientation of the muscle fibers, measured at the length for which the muscle produces its maximal isometric force. Fascicle length is measured instead of muscle belly length because muscle fibers in many muscles are oriented obliquely with respect to the long axis of the muscle belly.

Muscle Mass (m)

The amount of force that a muscle can produce depends on the total number of myofilaments arranged in parallel. Because myofilaments are densely packed through muscle fibers, this number is proportional to the physiological cross-sectional area (PCSA) of the muscle fibers. Because those fibers may be arranged in a pinnate form, the anatomical cross section of the muscle may not be perpendicular to all the muscle fibers and so would not reflect their true cross-sectional area. More reliable measurements can be made of the mass of the muscle, which can be converted to its volume by dividing by density. This volume must be the product of the length of the contractile elements (L_{ce}), which can be measured reliably by dissecting fascicles from the muscle, assuming that they are of uniform length (common) and at optimal length L_0 (any discrepancy can be

detected and corrected by observing sarcomere length under a microscope).

$$PCSA = \frac{m}{\rho L_{ce}}$$

Specific tension, ε , or maximal isometric force produced per unit of cross-sectional area (Spector et al. 1980; Lucas et al. 1987), has been shown to be the same across different fiber types (31.8 N/cm^2) and can be used to estimate maximal isometric force (F_0) using the following equation:

$$F_0 = \varepsilon * PCSA$$

Muscle fascicle length in the equation is set to L_0 , because ε is defined at that length. The modeled muscle's F_0 is used to scale the dimensionless relationships to obtain force output in absolute units.

Fiber Composition

Although maximal isometric force per unit area is roughly the same for different muscle fiber types, there are substantial differences in their contractile properties. Fiber types differ in terms of kinematic modulation of force output, rise and fall dynamics of contraction, and especially energy consumption. The recruitment order of motor units also depends on their fiber type. It is therefore important that different fiber types are modeled independently and that the fiber composition of the modeled muscle is known accurately.

Determining fiber composition is often challenging because of the many classifications of fiber types and because of the difficulty in measuring the attributes that distinguish them. Fibers differ mainly in terms of their myosin isoforms (namely, the myosin light and heavy chains) and the size of their sarcoplasmic reticulum and transverse tubule system that together influence force generation under dynamic conditions. There are also large differences in mitochondrial content and blood supply, which affect the metabolic cost of muscle contraction as well as the fiber's susceptibility to fatigue. All of these tend to covary in healthy muscle fibers but may become

heterogenous in muscle fibers that are diseased or undergoing trophic changes as a result of abnormal or rapidly changing usage patterns. Because differences in myosin heavy chain isoform and mitochondrial content have the largest physiological effects, they are used most commonly to classify fiber types. Slow-twitch (type 1) fibers have a different distribution of myosin heavy-chain isoforms than fast-twitch (type 2) fibers that leads to slower crossbridge kinetics, as evidenced by the relatively slow rate at which they hydrolyze ATP. Type 1 fibers and some type 2 fibers (namely, type 2a) have a high volume fraction of mitochondria, which can be assessed indirectly by measuring the concentrations of enzymes such as succinate dehydrogenase, for example, which is normally present in the mitochondria. These histochemical approaches require a tissue sample, which could be too invasive to obtain from humans. It is also worth noting that the results may be biased depending on the location in which it is obtained. Fast-twitch fibers tend to reside in the outer portion in muscle, so if a single sample is obtained from this location, the measurement would underestimate the percentage of slow-twitch muscle. There are also noninvasive methods for measuring fiber composition such as magnetic resonance spectroscopy, but to date they are relatively less accurate.

Characteristic Firing Rate of Muscle Fiber Type ($f_{0.5}$)

Muscles typically fire at rates ranging from $0.5f_{0.5}$ to $2f_{0.5}$, where $f_{0.5}$ is the firing rate at which muscle produces half of its maximal isometric force when its length is held at L_0 . $f_{0.5}$ is an important parameter because crossbridge activation relationships of different muscles that are normalized by this value become congruent, and therefore a generic relationship can be obtained. This is useful because only this parameter is needed to construct the entire crossbridge activation relationship for an arbitrary muscle to a high degree of accuracy. The actual firing rate behavior of motor units has been difficult to record, particularly at the higher levels of recruitment, so this useful normalization remains contentious.

Tendon + Aponeurosis Length (L_0^T)

The tendon plus aponeurosis is composed of tightly packed strands of collagen that are oriented in parallel with the long axis of the musculotendon. As in muscle, the amount a tendon can stretch depends on its length and the amount of force it generates in response to a stretch depends on its cross-sectional area. Longer tendons are composed of more collagen molecules arranged in series, each having similar material properties and dimensions, i.e., experiencing the same change in length in response to the same force. Longer tendons can therefore experience larger changes in length and will produce lower forces in response to the same stretch. The generic relationship of the series elastic element reflects the material properties of the constituent collagen fibers and should be scaled by the length of the tendon plus aponeurosis to be modeled. The length should be measured when muscle is exerting maximal isometric force on the tendon (L_0^T). If only the slack length of the tendon is known, then L_0^T can be estimated as 105% of tendon slack length.

Maximum Musculotendon Path Length ($L_{\max}^{MT}$)

As mentioned in "Parallel Elastic Element," the amount of passive force generated by muscle at a particular length correlates with its maximal anatomical length. Maximal anatomical length is defined as the maximal length a muscle can have across all anatomical configurations of the joints it crosses. This can be estimated by first measuring maximal anatomical length of the musculotendon and subtracting the length corresponding to the tendon (L_0^T).

Pinnation Angle

Muscle fibers of many muscles are oriented obliquely with respect to the tendon, and so not all of the force that they generate is transmitted to the bone segments. It is reduced by the cosine of the pinnation angle, with the remainder of the contractile force producing hydrostatic compression of the muscle. Even for relatively large pinnation angles, however, this loss in total force transmission in isometric muscle is relatively low (Scott and Winter 1991), so this model

does not account for this effect and does not require specification of pinnation angle. Modeling the effects of pinnation angle would be important for the relatively uncommon scenario in which it is large and changes rapidly by large amounts throughout a contraction, as it would alter the kinematics of the muscle fascicles, which in turn have a strong influence on force production.

Synonyms

[Final neurons of the descending auditory system](#); [Medial and lateral efferents](#); [Olivocochlear bundle](#); [Olivocochlear efferents](#)

Definition

Cochlear efferents are neurons that originate in the brainstem and terminate in the cochlea.

Detailed Description

Anatomy

In mammals, the final descending auditory pathways to the cochlea originate in the brainstem superior olivary complex and are called “olivocochlear efferents.” They are divided into two subsystems: the medial olivocochlear (MOC) and lateral olivocochlear (LOC) efferents (Fig. 1). MOC efferents originate in the medial part of the superior olivary complex and terminate mainly on outer hair cells (OHCs). LOC efferents originate in the lateral part of the superior olivary complex and terminate mainly on the peripheral processes (dendrites) of auditory nerve fibers under inner hair cells (IHCs) (Fig. 1, bottom). Efferent fibers also have branches that innervate other structures. Both MOC and LOC neurons receive inputs from other brain areas including higher auditory centers (not shown in Fig. 1).

In many species there are approximately twice as many MOC fibers that cross the midline and innervate the contralateral cochlea compared to the MOC fibers that are uncrossed and innervate the ipsilateral cochlea. In contrast, almost

all LOC fibers are uncrossed. An important difference is that MOC fibers are large and myelinated whereas LOC fibers are small and unmyelinated. One consequence of this is that electrical recordings have been made from the large MOC fibers (which showed that they respond to sound), but recordings have not been made from the small LOC fibers. Also, myelinated fibers are relatively easy to electrically stimulate, so electrical stimulation of MOC fibers has revealed what they do in the cochlea. In contrast, unmyelinated fibers have much

higher thresholds for electrical stimulation, and there are no similar direct stimulation studies that show what LOC fibers do in the cochlea.

MOC fibers are the effector neurons in a brainstem reflex pathway (Fig. 1, red, blue, and gold). The pathway starts with auditory nerve fibers that innervate neurons in the cochlear nucleus. Certain cochlear nucleus neurons (planar multipolar cells) send axons that cross the midline and innervate MOC neurons on the opposite side. These neurons form excitatory synapses on MOC neurons and appear to be the main

Physiology and Function of Cochlear Efferents, Fig. 1 An anatomical schematic of the olivocochlear (OC) reflexes to the right cochlea. *Top*: an outline of a transverse brainstem section showing the lateral OC (LOC green) and medial OC (MOC blue and red) neurons. Blue and red show the ipsilateral and contralateral MOC reflex pathways, respectively, until they join the olivocochlear bundle (OCB gold). Both MOC and LOC fibers form the OCB, which has crossed and uncrossed components. The OCB is accessible to stimulating

electrodes near the fourth ventricle (*at top*). *Bottom*: the afferent and efferent innervation to the organ of Corti: (1) olivocochlear lateral efferent fibers that synapse on Type I afferent fibers, (2) auditory nerve (AN) Type I afferent fibers that innervate inner hair cells, (3) olivocochlear medial efferent fibers to outer hair cells, and (4) AN Type II afferent fibers that form reciprocal synapses on OHCs and receive synapses from MOC fibers. (Modified after Fig. 8.1 of Guinan (1996) by permission of Springer-Verlag)

drive for the MOC acoustic reflexes that feed back to the cochlea. Since the dominant pathway from CN neurons to MOC neurons is crossed, the uncrossed MOC fibers carry the contralateral MOC reflex, and the crossed MOC fibers carry the ipsilateral MOC reflex (which crosses the midline twice). There is also evidence for a minor pathway from the cochlear nucleus to the MOC neurons on the same side which may account for most MOC neurons showing binaural properties, i.e., although MOC neurons are mainly excited by sound in one cochlea, sound in the opposite cochlea can also change the response (most often adding additional excitation).

In responses to tones, MOC fibers have V-shaped tuning curves much like those of auditory nerve fibers but somewhat wider. An individual MOC fiber innervates a place along the cochlea that has a best frequency similar to the MOC fiber's best frequency, i.e., the innervation is tonotopic. Although it has not been demonstrated physiologically or anatomically, it seems likely that MOC neurons in the brainstem are also tonotopically arranged.

Neurochemistry

The main neurotransmitter of olivocochlear efferents is acetylcholine (ACh), the same neurotransmitter found in peripheral nerve-muscle junctions. The MOC-OHC synapse is unusual in that it uses $\alpha 9$ - $\alpha 10$ ACh receptors and acts through a Ca^{++} -activated potassium channel (see Fig. 2). LOC-AN synapses use ACh but also have several other neurotransmitters and neuromodulators. Some LOC-AN synapses use the neurotransmitter dopamine. Little detail is known about LOC-AN synapses, but there is evidence that some may be excitatory and some inhibitory, actions which most likely reflect the two neurotransmitters, ACh and dopamine.

MOC Fast Inhibition

The most-studied effect of MOC fibers is a fast (time constant tens to hundreds of ms) inhibition of cochlear amplification (the process by which outer hair cells increase basilar membrane motion in response to low-level sounds). Since MOC action lowers cochlear amplification, a higher

Physiology and Function of Cochlear Efferents, Fig. 2 A schematic of a medial olivocochlear (MOC) synapse (purple) on an outer hair cell (OHC gray). The MOC terminal releases acetylcholine (ACh red) molecules which attach to $\alpha 9$ - $\alpha 10$ ACh receptors (dark blue) on the OHC. The $\alpha 9$ - $\alpha 10$ ACh receptors allow calcium ions (Ca^{++} blue circles) to enter the OHC, and these activate nearby Ca^{++} -activated potassium channels (dark green). These allow potassium ions (K^{+} green squares) to exit the OHC which hyperpolarizes the OHC and shunts OHC receptor currents, thereby reducing OHC motility and cochlear amplification

sound level is needed to achieve a given response level. The result is to shift responses toward higher sound levels; this effect that can be seen both in basilar membrane (Fig. 3a) and auditory nerve (Fig. 3c) responses to tones. Cochlear amplification, and therefore MOC inhibition, is largest in responses at the local best frequency (Fig. 3b, d). While most MOC effects can be explained by the reduction of cochlear amplification of basilar membrane responses, some cannot, e.g., inhibition at high sound levels or on the edges of tuning curves (Fig. 3e, f).

MOC innervation of the cochlea peaks in the mid-basal turn, and when MOC fibers are stimulated electrically, the largest MOC inhibition is seen in the corresponding frequency region (Fig. 4). The profile of MOC effect versus frequency in Fig. 4 is for cats. The corresponding pattern in humans is expected to be shifted 1–1.5 octaves lower in frequency due to human hearing covering a lower frequency range than cats.

MOC Slow Inhibition

When MOC fibers are stimulated over tens of seconds, an inhibition builds up that is called the MOC “slow effect” (Fig. 5). MOC fast and slow

Physiology and Function of Cochlear Efferents,

Fig. 3 MOC fast effects on basilar membrane (BM) motion and auditory nerve (AN) firing. *Left:* MOC inhibition shifts level functions to higher sound levels. *Right:* MOC inhibition usually has the greatest effect at the most sensitive frequency (b, d), but sometimes has the greatest effect at the edge of tuning curves (f). MOC activity was elicited by brainstem shocks. (a, b) Schematized from the data of Cooper and Guinan (2006). (c, e) Schematized from the data of Guinan and Stankovic (1996). (d) Schematized from the data of Guinan and Gifford (1988) and (f) from the data of Guinan and Gifford (1988) published as Fig. 3.3F from Guinan (2011) with permission from Springer Science+Business Media

Physiology and Function of Cochlear Efferents,
Fig. 4 MOC inhibition produced by electrical stimulation of medial efferent fibers in cats. MOC inhibition was measured as the threshold shift at an auditory nerve fiber's best frequency (cochlear frequency). Fibers were divided into low, medium, and high spontaneous rate groups. Each point shows the average over an octave band (adjacent points overlap data). In cats, medial efferent innervation peaks at about the 8 kHz region and has a profile along the cochlea like the inhibition of high and medium SR fibers. (Data from the work of Guinan and Gifford (1988))

effects inhibit both basilar membrane motion and auditory nerve fiber responses. However, basilar membrane responses are changed in opposite phase directions during fast and slow MOC effects, which shows that fast and slow effects originate predominantly from different mechanisms within the outer hair cells. MOC fast inhibition appears to be due to the hyperpolarization of OHCs and the shunting of OHC receptor currents produced by the MOC-OHC synapse's activation of Ca^{++} -activated potassium channels (Fig. 2). Application of ACh to isolated OHCs causes a slow decrease in OHC stiffness. The similarity of the slow time courses of the OHC stiffness change and the MOC slow effect suggests that the MOC slow effect is due to the change in OHC stiffness.

MOC Effects in Humans

All of the data shown above are from animals, and the MOC effects are from MOC activity produced

by electric shocks. In humans, you cannot excite the MOC efferents by shocks or record from auditory nerve fibers, but you can excite efferents by sound and record MOC effects by the change in otoacoustic emissions (OAEs). OAEs are sounds produced within the cochlea as a byproduct of cochlear amplification that travel backward through the middle ear and can be measured in the ear canal by a sensitive microphone. Since OAEs depend on cochlear amplification, and MOC activity turns down cochlear amplification, MOC activity reduces the amplitude of OAEs. Thus, the change in OAE amplitude can provide a measure of the MOC effect within the cochlea. OAE measurements are noninvasive and can be done in humans.

Activation of MOC efferents to one ear can be produced by sound in either or both ears (Fig. 6). This is consistent with the innervation pattern shown in Fig. 1 in that a given cochlea (the right cochlea in Fig. 1) receives sound-driven inputs from both ears. With sound in both ears, the MOC response is roughly the sum of the contributions from both sides (at least when the noise is the same in both ears).

The MOC-induced change takes time to build up and decay (Fig. 6). Across subjects the onset and decay time constants were 277 ± 62 and 159 ± 54 ms for contralateral broadband noise.

The onset and offset both started after delays of ~ 25 ms from the start or end of a noise burst. Little difference in time course was found for ipsilateral, contralateral, or bilateral elicitors. Considering the overall speed of the reflex, it seems best suited to operate on sound changes that last for 100 s of milliseconds. MOC reflex inhibition is too slow to act at a syllable by syllable rate on responses to speech.

MOC activation is a strong function of the bandwidth of elicitor sounds (Fig. 7). Broadband noise is the strongest elicitor; elicitor strength decreases as bandwidth decreases. This is true for ipsilateral, contralateral, and bilateral sounds. Note that since the overall elicitor level was kept constant as the elicitor bandwidth was increased, the energy density at each frequency decreases as bandwidth increases. These results indicate that the MOC reflex that affects one place on the cochlea summates excitation over almost the whole cochlea.

From experiments in animals, the ipsilateral reflex was expected to be twice as strong as the contralateral reflex. This is what was found for $\frac{1}{2}$ octave bands of noise (Fig. 7, red and blue points at the bottom left in each panel), but for broadband noise, the ipsilateral and contralateral reflexes elicited MOC inhibitions of similar strengths (Fig. 7, red and blue points at the right in each

Physiology and Function of Cochlear Efferents,

Fig. 5 MOC fast and slow effects both inhibit (i.e., reduce) basilar membrane (BM) motion (*top*), but they produce phase changes in opposite directions (*bottom*). The yellow areas show the period of MOC stimulation. Data at *left* and *right* obtained simultaneously. (From the data of Cooper and Guinan (2003))

Physiology and Function of Cochlear Efferents, Fig. 6 Representative MOC response magnitudes as a function of time from ipsilateral, contralateral, and bilateral elicitors from one ear of one subject. The elicitors were 50 dB SPL wide-band (0.1–10 kHz) noises with a 2.1 octave notch centered on the 40 dB SPL, 1 kHz probe tone. Points are data. Lines represent single exponential fits to the data with rise and fall time constants, τ_{rise} and τ_{fall} , shown in each plot. Each MOC response magnitude

was corrected for the measured noise, i.e., was estimated as the square root of (the magnitude of the change in the stimulus frequency otoacoustic emission ($|\Delta\text{SFOAE}|$) squared, minus the variance of the noise). The MOC response magnitude was set to zero when the noise variance was greater than $|\Delta\text{SFOAE}|$ squared. Responses were normalized by the magnitude of the SFOAE before the noise onset. (Unpublished data of Backus and Guinan (2006))

Physiology and Function of Cochlear Efferents, Fig. 7 MOC inhibition as a function of reflex elicitor bandwidth in humans. 60 dB SPL noise-band elicitors were centered on the frequency of the 40 dB SPL probe tones. The index of MOC inhibition was the magnitude of the change in the stimulus frequency otoacoustic emission $|\Delta\text{SFOAE}|$ normalized to the magnitude of the SFOAE

before the elicitor onset ($|\text{SFOAE}|$). To avoid interaction within the cochlea of the elicitor and probe responses, the MOC inhibition was measured in a 100 ms window starting 50 ms after the elicitor terminated. Error bars are standard errors of the mean. Horizontal lines: Solid mean noise-floor, BBN broadband noise (0.1–10 kHz, or 6.67 octaves). (From the data of Lilaonitkul and Guinan (2009))

panel). The crossed/uncrossed innervation ratio is not known for humans because determining this requires invasive experiments. However, from Fig. 7 it appears that sound bandwidth matters as much as the innervation ratio. Presumably, sound

bandwidth influences the way in which signals from the two ears are summated in the brainstem.

Another way in which the human and animal data differ is in their pattern across frequency. The typical result for shock-evoked MOC effects in

anesthetized cats and guinea pigs is a broad pattern of inhibition of auditory nerve responses that peaks near 8 kHz (Fig. 4). Translated to the frequency range of humans, this would be a peak near 4 kHz. Since shocks excite MOC fibers of all frequencies, the most comparable measurements in humans are those from broadband noise (e.g., the right-most points in Fig. 7). Taking note of the different vertical scale used at 4 kHz in Fig. 7, there is less MOC effect at 4 kHz than at 0.5 and 1 kHz. It has been a consistent finding that sound-evoked MOC effects measured in awake humans by changes in a variety of different otoacoustic emissions peak near 1 kHz. There are many differences in the techniques and conditions between the animal and human experiments, but the exact origin of the frequency of maximal MOC effect is not known.

The pattern of MOC inhibition across frequency depends on both the frequency of the sound that evokes the MOC activity and the place in the cochlea at which the MOC effects are measured (Fig. 8). For ipsilateral elicitors, the MOC inhibition occurs over a broad range but peaks near the frequency of the elicitor. In contrast, for contralateral elicitors, the largest MOC effects are elicited by sounds near 1 kHz no matter whether they are measured with low-, medium-, or high-frequency probes. Binaural

sounds elicit effects with intermediate frequency specificity. For bilateral sound, the magnitude of the MOC effect is typically close to the sum of the separate ipsilateral and contralateral MOC effects.

The strength of the MOC reflex varies across subjects. In a study of 25 subjects with good hearing and with MOC effects averaged long enough to get a statistically significant measurement in each subject, the MOC strength varied over a 5 to 1 range. Whatever benefit MOC inhibition has for hearing, it appears to vary across subjects (Fig. 9).

The Role of Efferents in Hearing

There may be many benefits of efferent activity but there is enough evidence to conclude that the following two efferent roles are important: (1) prevention of damage due to loud sounds and (2) helping to distinguish relevant sounds in background noise.

Animal experiments have shown that MOC efferents help to prevent hearing damage due to traumatic sound levels. When exposed to the same traumatizing sounds, guinea pigs with strong MOC reflexes had lower *permanent* threshold shifts than guinea pigs with weak MOC reflexes (Fig. 10). Other experiments have shown that exciting MOC efferents with shocks reduces temporary threshold shifts (TTSs). Both of these show effects of MOC efferents. Recent

Physiology and Function of Cochlear Efferents, Fig. 8 The MOC inhibition elicited by a $\frac{1}{2}$ octave band of noise depends on the frequency of the noise and of the probe tone. The noise bands were 60 dB SPL and the probe tones were 40 dB SPL. The index of MOC inhibition was the magnitude of the change in the stimulus frequency

otoacoustic emission $|\Delta SFOAE|$ (measured in a 100 ms window starting 50 ms after the elicitor terminated) normalized by the magnitude of the SFOAE before the elicitor onset ($|SFOAE|$). Error bars are standard errors of the mean. Solid line noise-floor mean, color coded as in the key. (From the data of Lilaonitkul and Guinan (2012))

Physiology and Function of Cochlear Efferents, Fig. 9 MOC inhibition varies widely across subjects ($n = 25$, mean = 37%, SD = 12%). MOC inhibition measured by the change in stimulus frequency otoacoustic emissions from a 40 dB SPL probe tone near 1 kHz. A 60 dB SPL contralateral wide-band noise elicited MOC activity. The line is a Gaussian fit to the data. (From the data of Backus and Guinan (2007))

experiments have shown that sounds that produce TTSs (probably due to damage in different cochlear structures than the TTSs noted above) can lead to long-term, permanent loss of auditory nerve fibers. This loss of auditory nerve fibers appears to come about because loud sounds cause an excessive release of neurotransmitter by inner hair cells which produces an excessive, indeed excitotoxic, flow of ions into the dendrites of auditory nerve fibers, which causes them to swell, burst, and degenerate. LOC efferents synapse on these auditory nerve fiber dendrites, and it seems likely that a major role of the LOC efferents is to reduce/prevent such damage. However, there is not, as yet, direct evidence that LOC fibers actually reduce or prevent the degeneration of AN fibers after acoustic trauma.

Many experiments have been done to look for efferent benefits in perceptual tasks. The most convincing evidence of an efferent perceptual benefit comes from animal experiments in which efferents were cut and their ability to localize sounds in noise decreased. In humans, a wide variety of experiments have been done trying to correlate increased MOC activity (measured with

Physiology and Function of Cochlear Efferents, Fig. 10 Strong MOC reflexes help to reduce noise-induced hearing damage. Permanent threshold shifts from 12 guinea pigs grouped by each animal's preexposure MOC reflex strength. Threshold shifts measured from auditory nerve compound action potentials. (Schematized from Fig. 5b of Maison and Liberman (2000))

Physiology and Function of Cochlear Efferents, Fig. 11 MOC stimulation can increase the signal-to-noise ratio of a signal relative to a masker. Lines show basilar membrane (BM) response with (thin red) and without (thick blue) MOC stimulation. The BM motion response to the higher-level signal (X) is reduced less than the response to the lower-level masker (O). (BM responses based on unpublished data of Cooper and Guinan)

otoacoustic emissions) with better performance in tasks involving the discrimination of a signal in noise. Both positive and negative results have been reported, even in tasks that look superficially similar. Overall, the data argue that MOC activity provides perceptual benefits, but the conditions under which a benefit is produced and the extent of that benefit are not yet clear.

Despite the lack of clarity in just how much perceptual benefit MOC efferents produce, there are two clearly understood mechanisms by which MOC efferents may produce such a benefit. For a moderate-level sound in a low-level noise, MOC efferents may increase the signal-to-noise ratio in the mechanical response of the basilar membrane. This increase in signal-to-noise ratio is produced because MOC efferents reduce the gain of cochlear amplification more at low sound levels than at high sound levels (Fig. 11).

Another mechanism by which MOC efferents may reduce noise masking (i.e., produce “unmasking”) takes place when there is a transient signal of interest in a background noise. In a silent background, MOC activity reduces cochlear amplification and shifts auditory nerve fiber responses to brief tone bursts to higher levels with little change fiber’s firing rate dynamic range (Fig. 12b). A background noise compresses this dynamic range by causing ongoing firing of the fiber which decreases the dynamic range available to signal-added low-level tone bursts – Fig. 12c. This background firing depletes the inner hair cell supply of vesicles which decreases the dynamic range at high tone levels (Fig. 12c). The net result is that a smaller change in output firing rate can be produced by a change in tone-burst sound level, i.e., the noise masks small changes in tone-burst level. Efferent stimulation

Physiology and Function of Cochlear Efferents, Fig. 12 MOC unmasking of auditory nerve fiber responses. Each panel shows rate versus level functions for a single auditory nerve fiber with sound conditions

coded by line styles as shown at the top of each panel. See text for further explanation. (Modified after Fig. 8.10 of Guinan (1996))

reduces the fiber response to the noise, which reduces the depletion of vesicles, with the net effect to be a partial restoration of the auditory nerve fiber's dynamic range, i.e., efferent unmasking (Fig. 12d).

Physiome Repository

Tommy Yu, Randall D. Britten, David P. Nickerson, Peter Hunter and Poul M. F. Nielsen
Auckland Bioengineering Institute, University of Auckland, Auckland, New Zealand

Definition

Physiome Repository (<http://models.physiomeproject.org>) is an online repository of mostly publicly available models and their associated data. Although models encoded in CellML are currently best supported, content in any format can be stored, retrieved, shared, and version controlled in the Physiome Repository (e.g., MATLAB m-files, C code, SBML, or NeuroML).

Detailed Description

The Physiome Repository originated as a generalization of the CellML model repository (Lloyd et al. 2008) to enable archiving, exchange, and collaborative development of computational models throughout the Physiome Project. Due to this history, models encoded in the CellML format still form the majority of the Physiome Repository content, with over 500 models currently publicly available. The software infrastructure underlying the repository is the Physiome Model Repository (PMR) software (Yu et al. 2011). The PMR software has specific support for CellML and FieldML, but it allows any electronic file to be

deposited, retrieved, and version controlled. As described later in this entry, the PMR software can also easily be extended to provide specific support for other model or data formats. The PMR software is an open-source software, and most content in the repository is freely available under a creative commons license. It also supports restricted access modes allowing the user who deposits the content to grant specific permissions (e.g., read/write) to specific users.

Revision Control

A key feature of the Physiome Repository is revision control, which relies on integration with the Mercurial distributed version control system (DVCS) (<http://mercurial.selenic.com/>). The CellML and FieldML model formats enable modularity by allowing models to be decomposed into multiple files. This feature is often used in other model and data formats as well. Within a set of related files, it is important to keep the files consistent with one another, which is achieved using the PMR software's revision control features. These allow files to be grouped into "workspaces," each of which is a version-controlled folder along with its contents and sub-folders. The set of related files in a workspace can be retrieved in the state that they were at for any recorded revision in the history. Revision control also assists with data provenance, recording who made each change, and the reason, captured each time a user commits a change to the version control system and manually enters a comment describing the reason. The use of a DVCS enables version-controlled collaboration between multiple users allowing model development to take place independent of the Physiome Repository but preserving the version history when these changes are "pushed" back into the Physiome Repository.

Model Presentation

"Exposures" are used to highlight specific revisions of a workspace, for example, when a

particular revision represents the state of a model at the time of a research publication about the model or has been vetted by a user performing the role of a curator. Importantly, exposures create a persistent URI, which unambiguously identifies a specific version of a workspace and provides the basis for uniquely locating all resources relevant to that exposure. Furthermore, for data formats that have customized exposure plug-ins, the user is able to select enhanced options that control the generation of user-friendly web pages for the model during the exposure creation process. For example, for each CellML model exposure, the mathematical equations for that model are displayed, as well as descriptive text about the model, and an associated diagram, as well as the equivalent computer program code which is automatically generated for the CellML model in a selection of programming languages (MATLAB, Python, C, and Fortran).

Underlying Software

The PMR software is constructed on top of a content management framework called Zope (<http://www.zope.org/>), with all content management aspects surrounding the handling of models and related data using the content management system called Plone (<http://plone.org/>), which is also built on top of Zope. Each feature of the PMR software is constructed as a set of plug-ins on top of the Zope/Plone system. These plug-ins provide the core functionality of the Physiome Repository: collaborative development and data exchange. Support for additional model and data formats, or alternative DVCSs, can be achieved by creating the required plug-ins.

PhysioNet

George B. Moody
Harvard-MIT Division of Health Sciences and
Technology, Massachusetts Institute of
Technology, Cambridge, MA, USA

Definition

PhysioNet (<http://physionet.org/>) is a resource for research and education that provides free access to numerous large collections of recorded physiologic signals and time series and related open-source software for exploration and analysis of them, in support of basic, clinical, and applied research in medicine, physiology, public health, biomedical engineering and computing, and medical instrument design and evaluation. Although best known for its critical care, ECG, and cardiovascular data collections, PhysioNet curates a wide variety of data collected and contributed by neuroscientists, clinical neurologists, and researchers in allied disciplines.

Detailed Description

PhysioNet has three major components.

PhysioBank holds more than 60 open-access data collections as of 2013, containing physiologic signals and time series collected from roughly 36,000 human subjects and amounting to more than 4 TB in all. The recordings include cardiopulmonary, neural, and other biomedical signals from healthy volunteers of all ages as well as patient cohorts with conditions

including epilepsy, neurodegenerative diseases, sleep and gait disorders, congestive heart failure, sudden cardiac death, organ failure, trauma, and more.

PhysioToolkit includes software components for data visualization, interactive waveform annotation, data mining, importing and exporting data, deidentification, signal and time series analysis (including QRS and BP pulse detectors, derivation of respiration from the ECG signal, atrial fibrillation detection, apnea detection, IPFM tachometry of heart rate, standard and novel measures of heart rate variability, cardiac output estimation, and T-wave alternans detection and quantification), linear and nonlinear filters, signal averaging, frequency domain analysis of evenly and unevenly sampled time series, detrended fluctuation analysis, multiscale entropy, information-based similarity classification, multifractal analysis of time series, sample entropy, lumped parameter models of the heart and circulation for research and education, and realistic ECG waveform generators, as well as libraries of functions to provide uniform access to PhysioBank-compatible data either from local files or directly from Web servers for user-written software in C, C++, Fortran, Java, MATLAB, Octave, Perl, and Python. All PhysioToolkit software is available in source form under the GNU General Public License (GPL).

PhysioNetWorks is an online laboratory that provides workspaces for researchers to develop contributions that will be made publicly available via PhysioNet when complete. Unlike other areas of PhysioNet, these workspaces are password protected. During the active phase of research, data can be deposited securely; shared with selected collaborators; analyzed, annotated, and indexed using software provided by PhysioNet or by the research team; and documented. When the development is complete (often when the major results of the study are published), the project's contributions are reviewed and posted in PhysioNet's public archives; data go to PhysioBank and open-source software to PhysioToolkit.

Background

PhysioNet was founded in 1999 (Goldberger et al. 2000) by a team of researchers and clinicians headed by Ary L. Goldberger (a professor of medicine at Harvard Medical School and a cardiologist at Boston's Beth Israel Deaconess Medical Center) and Roger G. Mark (a professor of electrical engineering and computer science at MIT, former cochair of the Harvard-MIT Division of Health Science and Technology, and a physician). Mark, Goldberger, and their colleagues are long-time collaborators whose research throughout the previous 20 years had led them to create a series of meticulously characterized data sets, beginning with the MIT-BIH Arrhythmia Database (Moody and Mark 2001), which they had shared with several hundred interested researchers and medical instrument developers via digital tapes and CD-ROMs. The advent of the World Wide Web and widely available high-speed networking offered an opportunity for data sharing on a far larger scale. With support from the US National Institutes of Health (initially via the now-defunct National Center for Research Resources and, since 2006, from the National Institute of Biomedical Imaging and Bioengineering and the National Institute of General Medical Sciences), PhysioNet was established as the outreach component of the Research Resource for Complex Physiologic Signals (Moody et al. 2001, 2011).

Activities

Eleven data sets contributed by the PhysioNet team established PhysioBank. The software they had developed for exploring and analyzing these data sets became the core of PhysioToolkit. By late 2013, their collaborators and many other researchers had donated over 50 more data collections and numerous software packages, and over 60 PhysioNetWorks projects were developing additional data and software resources.

The PhysioNet team's strong support of open data formats, open-source software, and unrestricted access to PhysioNet's content led to the early development of an exportable infrastructure composed entirely of open-source

components. This choice was made to encourage replication of PhysioNet and led to development of a worldwide network of volunteer-operated PhysioNet mirror sites within a few years. These sites provide fast local access to PhysioNet's content and Web services to their maintainers and their colleagues, especially from locations where network connections to the master servers at MIT may be unreliable or slow.

The PhysioNet/CinC Challenge, an annual series of open engineering challenges, was inaugurated for the IEEE EMBS-sponsored conference, *Computers in Cardiology* (now *Computing in Cardiology*, or CinC), which was hosted by the PhysioNet team at MIT in September, 2000. The challenge topic is chosen each year to focus on an unsolved or poorly solved problem that can be addressed using data provided via PhysioNet. The challenges lower the barrier to participation by researchers and students who would otherwise lack access to relevant data and by focusing attention on achievable solutions that can be evaluated and compared objectively using freely available reference data. Challenge topics have included detecting sleep apnea from the ECG (Moody et al. 2000; Penzel et al. 2002); predicting the onset and spontaneous termination of atrial fibrillation; predicting acute hypotensive episodes in intensive care unit patients (Moody and Lehman 2009); developing robust methods for filling gaps in multiparameter physiologic data (including ECG signals, continuous blood pressure waveforms, and respiration), with applications in detection of clinically important events and in reduction of false alarms in the ICU (Moody 2010); predicting mortality of ICU patients (Silva et al. 2012); and noninvasive fetal ECG (Silva et al. 2013), among others.

fundamental quality of a visual stimulus. It is very important to remember that pitch is a subjective quality that is constructed in the brain of a listener, not a physical quality of a sound wave. This subjective quality makes precise definitions troublesome. The American National Standards Institute defined pitch as “that attribute of sound which allows sounds to be ordered on a scale from high to low.” However, this definition is problematic because it remains mute about who or what is supposed to do the ordering, and as we shall see, there can be more than one “up” direction. Perhaps a more useful operational definition is to think of pitch as that property which carries melody in music. With that definition in mind, sounds can be assigned a **pitch value** which could be specified in terms of the corresponding “musical note” (e.g., A4) or equivalently in terms of the corresponding fundamental frequency (e.g., 440 Hz).

Note that just as the color of a visual stimulus can be faint or pale or indistinct, the pitch of an auditory stimulus can similarly be unclear. Some sounds have no discernible pitch at all (white noise, clicks); others have more or less clear pitches. **Pitch salience** (or pitch strength) might be thought of as equivalent to color saturation. Consider a rushing noise with faint whistling component as an example of a sound with low pitch salience. Furthermore, even salient pitches can be unclear due to possible **pitch ambiguity**.

Pitch Perception, Models

Jan Schnupp
 Department of Physiology, Anatomy and
 Genetics, Medical Sciences Division, University
 of Oxford, Oxford, UK

Definition

Pitch is a fundamental perceptual quality of an acoustic stimulus, perhaps not unlike color is a

Detailed Description

Which Attributes of Sound Determine Its Pitch?

Whether or not a sound has a salient pitch appears to depend chiefly on its **periodicity**. Sounds are periodic if the sound wave exhibits a motif that repeats. Sine waves or regular click trains are good examples. In nature, periodic sounds often arise as ► [Pulse-Resonance Sounds](#). The repeated motif must roughly be between 33 and 0.25 ms long. The sound’s fundamental frequency corresponds to the inverse of this motif length, resulting in pitch values between 30 and 4,000 Hz. Fundamental frequencies below this range lead to the perception of a beating rhythm rather

than a constant pitch. At fundamental frequencies above this range, sounds still sound pitchy, but pitch discrimination thresholds increase substantially. Also, the motif must be repeated at high fidelity. If the repeat is only approximate (as in narrow band noise), the pitch salience declines. If the sound wave is self-similar over several time delays, the pitch can become ambiguous.

This emphasis on periodicity suggests that determining the pitch of a sound wave should be done using a **time domain analysis** of the waveform. For example, one could calculate the **auto-correlation** function of the sound wave, and indeed some electronic tuners operate in this manner to calculate the fundamental frequency of a musical sound. For periodic sounds, the autocorrelation function will exhibit prominent peaks at time intervals which predict the perceived pitch rather well. However, **frequency domain analysis** can also work because strictly periodic sounds (consisting of a very faithfully repeated waveform motif) necessarily exhibit Fourier spectra with prominent peaks at frequencies which are harmonics (integer multiples) of the sound's fundamental frequency. In other words, the spectra of periodic sounds exhibit **harmonic structure**, and it should in principle be possible to predict the pitch a sound evokes from the position or spacing of harmonic peaks.

Both autocorrelation and frequency domain analysis can also be used in an attempt to explain the phenomenon of **pitch equivalence**. Many musical instruments traditionally produce notes with fundamental frequencies spaced at “semitone” intervals, where a semitone corresponds to 1/12th of an octave, and one octave is a doubling or the fundamental frequency. Notes separated by one or several octaves tend to be perceived as in some sense “equivalent” (they have the same “pitch chroma”), and one instrument playing, say, the note A3 (with a fundamental of 220 Hz), could be said to play “in unison” with another that plays A5 (two octaves higher, at 880 Hz). This perceptual equivalence is perhaps less surprising if one realizes that although the waveforms of these two sounds may look very different, they will have many peaks in common when analyzed with either an autocorrelation of a frequency spectrum.

Timing and Place Theories of Pitch

The fact that either frequency or time domain cues could be used to inform pitch judgment led to competing **place theories** and **timing theories** of pitch (Licklider 1951). Place theories propose that the brain analyzes travelling wave peaks on the basilar membrane of the cochlea to infer harmonic structure. Timing theories propose that the brain might analyze inter-spike intervals of phase-locked auditory nerve fiber responses to achieve something akin to an autocorrelation analysis. Several observations are difficult to account for in place theories, including the pitch of **missing fundamental stimuli**, sound level dependence of cochlear travelling wave peaks, and limited resolution of the cochlear frequency place code leading to “unresolved harmonics.” While these difficulties have led to timing theories being perhaps more popular, so far there is no good physiological evidence for either place- or timing-based analysis in the auditory brainstem. Also, it is of course possible that both time and place information contribute to pitch percepts, just as interaural time and level differences contribute to source direction percepts. Indeed, it is possible that place and timing cues contribute to pitch perception in different ways, as suggested from recent work in cochlear implant patients. With cochlear implants, it is possible to stimulate one place on the cochlea with pulses of varying rates or to stimulate various places at the same rate. Interestingly, cochlear implantees will report that the evoked sound percepts sound “higher” either if the location of the cochlear stimulation moves toward the base while the stimulation rate is held constant or if the stimulation rate is increased but the location is held constant. So both place and rate influence the reported “pitch,” but multi-dimensional scaling analysis of sound similarity ratings suggests that “place pitch” and “periodicity pitch” may correspond to different “up” directions in “perceptual space” (Chen et al. 2005). This may seem bizarre, but it is important to remember that the manner in which perceptual data are collected is not always unambiguous. For example, a very widely used method in psychophysics is the two alternative forced-choice

(2afc) test. Subjects are presented with two sounds and must decide which one “sounds higher” to them – often without much further instruction as to what “higher” means or without feedback. Also, in these tests, subjects are not allowed to answer “I cannot tell – they sound more or less the same.” Instead, they are instructed to guess if they are uncertain. In such a setting, if you present subjects with the two words “soon” and “seen,” both sung as the same note, and forced them to decide which sounds higher even though their fundamental frequency was the same, most would indicate “seen” as “sounding higher” than “soon.” This is a natural choice given that the vowel/ee/comprises higher-frequency formants than the vowel/oo/. But/ee/at $F_0 = 110$ Hz is “higher” than/oo/at 110 Hz in the sense that its “spectral centroid” is higher while the fundamental is the same, while/ee/at $F_0 = 220$ Hz is “higher” than/ee/at $F_0 = 110$ Hz in the sense that the fundamental, and hence the harmonic structure, is higher, while the spectral centroid is the same. These differences manifest as quite distinct perceptual qualities, but this important qualitative difference can easily be lost in 2afc experiments based solely on pairwise comparisons. (Readers can experience this themselves at <http://auditoryneuroscience.com/topics/two-formant-artificial-vowels>).

Presumed Neural Coding for Pitch by Neurons in the Central Auditory System

Since periodicity is an important cue for pitch, many neurophysiologists have studied periodicity tuning among auditory neurons in the brainstem, midbrain, and cortex as a possible substrate for pitch representations. A number of studies have suggested that the periodicity of tuned neurons may form topographically ordered “periodotopic maps” in the inferior colliculus (Schreiner and Langner 1988; Baumann et al. 2011) or cortex (Schulze et al. 2002), with a periodotopic map running orthogonal to the tonotopic axis. The idea of a periodotopic or pitch map in the brain is attractive, as such a structure might serve to

physically separate out different sound sources according to pitch cues. However, data collected by other researchers (Nelken et al. 2008) does not support the idea of periodotopic maps, and while a topographic pitch map is an appealing idea for human observers who would find such a map easy to read, it might provide little benefit to downstream neural networks which would read out such a map through a tangle of heavily divergent and convergent connections.

Whether the central nervous system uses topographic maps to represent pitch is not the only question that remains controversial. Whether topographically organized or not, many researchers have argued that the auditory cortex in particular may have subfields that are dedicated to processing or representing (or perhaps more accurately, creating the percept of) pitch (Griffiths et al. 1998). Some authors have even gone as far as declaring that they identified “pitch neurons” in a narrowly circumscribed “pitch area” in the marmoset cortex (Bendor and Wang 2005), and while their study documented some very interesting periodicity tuning properties in cortical neurons, it remains unclear whether these neurons play any role in forming or signalling subjective pitch percepts. Indeed, other studies which have tried to elucidate whether sensitivity to pitch cues is indeed confined to dedicated neural populations or rather coexists as a **widely distributed representation** intermingled among sensitivity to other auditory attributes such as timbre or sound source direction have found more evidence for the latter than the former (Bizley et al. 2009; Walker et al. 2011), and one of the very few studies that has attempted to link electrophysiological responses in the cortex to subjective pitch judgments for complex sounds similarly found pitch-related responses to be quite widely distributed over large parts of the auditory cortex (Bizley et al. 2013).

Neurocomputational Models of Pitch Perception

Modelling the neural processing of pitch perception has a long history. As mentioned above,

thinking about pitch processing has been dominated by “place theories” which try to discover harmonic structure in the spectral representation of the sounds and “timing theories” which are based on an analysis of the autocorrelation of the sounds. Both these approaches have given rise to many neurocomputational modelling approaches. An extensive review is beyond the scope of this article (interested readers are referred to de Cheveigne 2005), but we might mention “harmonic sieve” pitch template matching (e.g., Shamma and Klein 2000) as a representative example of a place-coded approach, while “summary autocorrelation models” (e.g., Meddis and Hewitt 1991) are representative of a time-coded methods. Of course, time- and place-based methods are not necessarily mutually exclusive, and as early as the 1950s, Licklider proposed a “duplex model” combining both place coding and temporal coding elements. The numerous models that have been proposed vary greatly in their complexity, in their attempts to incorporate “physiological realism,” and in their ability to account for the wide range of pitch-related perceptual phenomena, such as pitch ambiguity in inharmonic sounds, or the apparent ability of the auditory system to extract pitch information on varying time scales. The latter is an interesting case in point. Intuitively, the reader may appreciate that any pitch extraction algorithm may be able to determine pitch with greater accuracy if it can operate over long time scales and thus average over a larger sound sample. However, if the sounds to be analyzed change very rapidly, then algorithms integrating over long time periods will be too sluggish. There is a trade-off to be made between precision and speed, and some of the most sophisticated models developed to date (Balaguer-Ballester et al. 2009) incorporate top-down elements which adapt the time constants of the pitch extraction algorithm to the temporal dynamics of the sound. The development of ever more sophisticated models continues to this day.

Polarization Vision

Stanley Heinze

Department of Biology, Lund University, Lund,
Sweden

Definition

Polarization vision is the ability of animals to detect the oscillation plane of the electric field vector of light (*E*-vector) and use it for behavioral responses. This ability is widespread across animal taxa but is particularly prominent within invertebrates, especially arthropods. Polarized light can be either used implicitly for enhancing image contrast and for adding another dimension to the color vision system, or it can be explicitly used as a separate vision channel for communication purposes and for encoding global directions for an internal compass. Polarized light in nature is produced either by reflection at shiny surfaces or by scattering (e.g., in the atmosphere) of unpolarized sunlight. This results in the presence of polarized light in many different habitats, including underwater. The most prominent source of polarized light is the skylight polarization pattern, which contains information about the position of the sun in the sky and is thus used for navigation purposes. In insects, *E*-vectors are detected through specialized regions of the compound eyes. Neurons downstream of the involved photoreceptors respond to changes in *E*-vectors with modulations of their action potential frequency, so that each neuron is tuned to one particular *E*-vector. Over the last decade, an extensive, conserved network of such neurons has been uncovered in the brains of locusts, crickets, and monarch butterflies, spanning many processing stages, from the photoreceptors to the motor control centers in the thorax. At the boundary of sensory processing and motor planning, a brain region called the central complex plays an integral part in polarized-light processing. It comprises an ordered array of neurons that use polarized-light information to encode a representation of the azimuthal space surrounding the animal. How this

network is proposed to process polarized-light information, integrates it with other sensory modalities, and transforms sensory signals into motor commands that guide behavior is the main focus of this entry. To put this neuronal network into the context in which it has to function in the natural world, results obtained from behavioral experiments in a variety of species are discussed as well.

Detailed Description

One of the defining features of higher animals is their ability to actively move through their environment in order to search for food, escape from predation, or find mating partners. To achieve these behaviors, an animal has to be able to use the available sensory cues to extract information about its current direction of movement and its position relative to other objects in the surrounding space. Visual information plays a dominant role in many animals for guidance of orientation behavior. One cue that can be used by many insects is polarized light. Like color and brightness, the plane of polarization (oscillation direction of the electric field vector (*E*-vector)) is a fundamental feature of light and contains information that can be utilized for guiding behavior. Like bright or colorful objects, objects that emit light with particular *E*-vector orientations may be attractive or repulsive for an animal. This can be used for finding ovipositing sites (e.g., in butterflies) (Kelber et al. 2001; Kelber 1999), for intraspecific communication signals (e.g., in marine invertebrates like mantis shrimp, fiddler crabs, or cephalopods) (Marshall et al. 1999; Chiou et al. 2008), or for detecting suitable habitats (e.g., bodies of water found through polarized light by the back swimmer) (Schwind 1991). Additionally, sunlight scattered in the upper atmosphere, i.e., the blue skylight, contains *E*-vector information that is directly linked to the position of the sun. For animals that exhibit complex behaviors such as central place foraging (returning to a nest after extended foraging trips) or long-distance navigation (e.g., migration to overwintering grounds), the information provided by the position of the

sun provides a global frame of reference and can therefore be used to improve the accuracy of these orientation behaviors (Wehner 1984; Horváth and Varjú 2004).

Behavioral experiments with ants and bees (particularly in the desert ant *Cataglyphis* and the honeybee *Apis mellifera*) have revealed that polarized light is indeed used to infer the position of the sun and guide the animal back to the nest after foraging trips (Wehner and Labhart 2006). In the monarch butterfly, polarized light can also be used to help maintaining a southeasterly flight bearing during the spectacular mass migration of this species from northeastern North America to Central Mexico (Reppert et al. 2004; Merlin et al. 2012). In many other insects, adjustment of flight/walking direction in response to artificial polarized-light stimuli has been described as well (desert locust, Mappes and Homberg 2004; field cricket, Brunner and Labhart 1987; several fly species, Philipsborn and Labhart 1990; Wolf et al. 1980). Interestingly, in nocturnal dung beetles, even the faint polarization pattern around the moon is used for maintaining a straight course when navigating away from a pile of dung with a freshly made dung ball (Dacke et al. 2003).

Although the characteristics of the behavioral responses to polarized light have been studied in great detail in ants and bees, little is known about how this information is processed in the brains of these insects. Nevertheless, computational principles about how polarized light is processed to produce the observed behavior have indirectly been concluded from clever behavioral experiments. These indirect findings now remain to be confirmed by direct physiological evidence from polarization-sensitive neurons in the brains of these species. Recently, however, such data has been collected from species that are less well understood behaviorally but much more accessible for electrophysiological experiments: the field cricket, the desert locust, and the monarch butterfly (Homberg et al. 2011). The extensive dataset resulting from the work in these three species provides insight into how polarized light is detected, processed, integrated with other sensory modalities, and finally sent to the motor centers of the nervous system to ultimately guide behavior.

These findings are likely relevant across a wide range of insects and might underly the well-studied behavior of bees and ants as well. The characteristics of the involved neurons and the computational principles revealed by studying the network they comprise are therefore the major focus of this entry.

Polarized Light in Nature

Light is an electromagnetic wave and consists of an electric and a magnetic field vector oscillating orthogonally to each other. Both vectors oscillate perpendicular to the propagation direction of the light beam. Light emitted by the sun is unpolarized. That means that the electric field vectors (*E*-vectors) oscillate randomly in all directions. As the *E*-vectors exhibit axial symmetry, the range of all possible *E*-vector orientations is 180°. Linearly polarized light comprises *E*-vectors all oscillating in the same direction (Fig. 1a). When linearly polarized light is passed through a quarter wave retarder, it becomes circularly polarized light. This form of light can be viewed as consisting of two oscillations with *E*-vector orientations orthogonal to each other and out of phase by a quarter of their wavelength (Fig. 1a). When the observer faces the light beam, the tip of the resulting *E*-vector therefore moves along a circular path. In cases in which the two *E*-vector components are out of phase by a different value, the *E*-vector moves along an elliptical path, producing elliptically polarized light. Linearly polarized light is produced when both *E*-vector components are in phase. Aside from the plane of oscillation, the second important characteristic of polarized light is the degree of polarization, i.e., the ratio of polarized to unpolarized light within a beam of light (between 0% and 100%).

In nature, linearly polarized light is produced from sunlight either by scattering or by reflection at shiny, dielectric surfaces. In air, polarized light thus results from reflections at shiny leaves, animal fur, and water surfaces or by scattering of sunlight by molecules of the atmosphere (Horváth and Varjú 2004). While polarized light

Polarization Vision, Fig. 1 The nature of polarized light and the principle of detecting polarized light in insect photoreceptors. (a) Schematic illustration of the transformation of unpolarized light (right; all planes of oscillation occur) to linearly polarized light (middle; only one oscillation direction occurs) and finally to circularly polarized light (left; direction of oscillation rotates over time). (b) Schematic drawing of an insect photoreceptor and its preferred plane of polarization. Parallel microvilli unilaterally protruding from the cell body form the rhabdomere. Photopigments are embedded in the microvilli membranes (enlargement) and preferentially absorb incoming light

oscillating in one particular plane (indicated by *double arrows*) (Modified from Wehner 1976). (c) Light waves oscillating in parallel to the excitable double bond (between carbon 11 and 12, red) are preferentially absorbed by the photoactive chromophore 11-*cis*-retinal. This photoconversion results in formation of all-*trans*-retinal and to the activation of a downstream signal transduction cascade. The position of retinal is fixed in space by the surrounding protein component of rhodopsin (opsin; not shown) and thus provides the molecular basis for polarization vision

resulting from reflections at water surfaces is dominated by horizontal *E*-vector orientations, polarization in the sky forms a characteristic *E*-vector pattern (Fig. 2). In this pattern, the *E*-vectors are arranged in concentric circles around the sun, with the highest degree of polarization located 90° away from the sun, reaching 75% under optimal conditions. Light close to the sun (and the “antisun” in the opposite sky

hemisphere) is unpolarized. As the *E*-vector pattern in the sky is directly linked to the position of the sun and follows its apparent movement across the sky over the course of the day, it can be used to localize the sun even when only a small patch of blue sky is visible (Fig. 2b, c). A similar *E*-vector pattern is present around the moon, albeit several orders of magnitude dimmer. The fact that the position of the sun can be inferred from viewing

Polarization Vision, Fig. 2 Polarization pattern of the sky. (a) Schematic representation of skylight *E*-vector pattern. Orientation of lines illustrates *E*-vector angles, while the thickness of the lines represents degree of polarization. (b) *E*-vector orientation for different solar elevations. Note that at low elevations, *E*-vectors are oriented in parallel

throughout the sky. At the zenith, the *E*-vector orientation is always perpendicular to the solar azimuth. (c) Degree of polarization for different solar elevations. Note that at high solar elevations, areas of high degrees of polarizations can only be found close to the horizon

E-vectors of the blue sky is exploited by animals for compass navigation and orientation and comprises the best-understood function of polarized-light vision (Wehner and Labhart 2006; Merlin et al. 2012; Wehner 2001).

Other than in air, polarized light is also present within bodies of water (Cronin and Marshall 2011). Here, the difference in refractive indices of air and water results in the compression of the 180° dome of sky into an angle of 97.2° when viewed from under the water surface. This region is called Snell's window and contains the skylight polarization pattern similarly to above the water surface. Outside this critical angle, polarized light is produced by scattering of sunlight by the water itself and results in mostly horizontally oriented *E*-vectors. The degree of polarization underwater rarely exceeds 50%.

Concepts Deducted from Behavioral Data

Behavioral responses to polarized light have been investigated in many species and have revealed

details about how animals, particularly invertebrates, process polarized-light cues. Most work has been carried out in those insects, in which polarized light is used for navigation purposes. The ability of these animals to detect and respond to changing *E*-vectors was shown in experiments, during which a rotating polarizer was placed above a tethered animal during flight or walking behavior. In response to the rotating polarizer, crickets (Brunner and Labhart 1987), houseflies (Philipsborn and Labhart 1990), fruit flies (Wolf et al. 1980), and locusts (Mappes and Homberg 2004) try to align their body length axis with a particular *E*-vector. This results in approximately sinusoidal changes of their (fictive) forward movement direction in phase with the rotating polarizer, a behavior called polarotaxis. Importantly, this polarotactic behavior is abolished (done in locusts and crickets), when a small part of the compound eye, the dorsal rim area (DRA), is painted over but is left intact, when the complete compound eye except for the DRA is covered. These data show that at the level of the eyes, the DRA of these insects is both sufficient and necessary for generating orientation responses

based on *E*-vector information and confirms much earlier data from similar experiments in freely moving bees and ants (Wehner and Strasser 1985; Duelli 1975). In locusts, such experiments have been combined with surgical brain lesions and revealed that the anterior optic tract is necessary for processing the polarized-light information needed for polarotaxis in the brain (Mappes and Homberg 2007). In crickets, polarotactic behavior was further used to delineate the spectral range of polarization vision, its absolute sensitivity, and its reliability under low degrees of polarization. These studies revealed that these insects are using blue light for detecting *E*-vectors and can reliably respond to polarized light under very dim conditions (below light levels of a moonless night) (Herzmann and Labhart 1989). Additionally, even at degrees of polarization as low as 7%, crickets are able to perform polarotactic behavior (Henze and Labhart 2007). The preferred *E*-vector angles in locusts and crickets cover a wide range, are variable between individuals, and even change between trials. This indicates that polarotaxis is not merely a stereotypical alignment response resembling activity maxima or minima in the eye's *E*-vector detection system but that the animals have the ability to actively maintain an orientation matching the angle of any *E*-vector.

Responses to natural skylight polarization patterns have been tested in tethered preparations of monarch butterflies (Reppert et al. 2004; Stalleicken et al. 2005) and the fruit fly *Drosophila* (Weir and Dickinson 2012). Both species were placed in flight simulators with a clear view of the sky, and the skylight polarization pattern was changed by 90° either by rotating the simulator (*Drosophila*), using a liquid crystal device (*Drosophila*), or by inserting and rotating a polarizer sheet above the animal (monarch). In both species, the rotation of the skylight polarization pattern resulted in an adjustment of the flight orientation in the predicted direction in at least a subset of the tested animals. While the population of tested monarch butterflies was oriented in a common direction (in tune with their southwesterly migratory direction), the straight flight segments of the flies did not show such a common orientation (Reppert et al. 2004; Weir and

Dickinson 2012). By using appropriate filters, it was shown that the ultraviolet (UV) range of the spectrum is necessary and sufficient for the monarch butterfly (Sauman et al. 2005). UV light is also sufficient for *E*-vector responses in *Drosophila*, but the behavior can additionally be elicited with blue light (Weir and Dickinson 2012). Similar responses to longer wavelengths have also been documented in an assay that uses a population alignment response to artificial *E*-vectors in *Drosophila*. Whereas dorsally presented light only elicited a response in the UV range, ventrally presented light was additionally efficient at blue and green wavelengths (Wernet et al. 2011). This data therefore also revealed that the DRA cannot be the only eye region involved in detecting polarized light at least in *Drosophila*.

Detection of polarized light in the ventral visual field has also been described in insects that seek water bodies for habitat selection or reproduction. When flying, these animals (e.g., back swimmers, female horseflies, water beetles) are strongly attracted to surfaces emitting horizontally polarized light, whereas other *E*-vector orientations are not attractive (Schwind 1984, 1991; Horváth and Varjú 2004). Naturally, water surfaces are the dominant source of horizontally polarized light, but these insects are easily tricked into landing on man-made polarizing surfaces, illustrating that it is indeed the horizontal *E*-vectors that provide the attraction.

Underwater, stomatopod crustaceans (mantis shrimps) are the most extensively studied invertebrates in relation to polarization vision (Marshall et al. 1999; Marshall 1988; Marshall and Cronin 2011). In learning experiments (simple choice experiments with food reward), it was shown that these animals have the ability not only to detect linearly polarized light but also to respond to circularly polarized light (Marshall et al. 1999; Chiou et al. 2008). Both forms of polarized light are reflected by body parts of mantis shrimps, and this system is thus thought to serve intraspecific communication purposes. Due to the uniform background of mostly horizontally polarized light underwater, linear polarization vision is also suited to enhance contrast and possibly to facilitate prey detection in these habitats.

The best-studied models for polarization vision, however, are the honeybee and the desert ant. Both species are central place foragers and exhibit a behavior called path integration, i.e., they return to their nest in a straight line after a complicated foraging trip. To achieve this, they have to monitor both the distance traveled on the outbound journey and all changes in direction. This information is used to continuously update their homing vector. For monitoring directional changes, bees and ants use the sun and the sun-derived polarization pattern of the sky (Wehner 1984, 1989, 2003). Over several decades, an extensive set of complex behavioral experiments, particularly in bees, has led to knowledge about the internal representation of the sky and how this information is used. In one of the most crucial experiments, bees were trained to learn the route to a feeder in the vicinity of their hive, while the animals could see the complete skylight polarization pattern. When the bees tried to communicate the azimuthal position of the feeder to their nestmates (by performing the waggle dance), only a single *E*-vector was present. The communicated azimuth thus allowed to determine where in the sky the bee estimated the position of the presented *E*-vector (Rossel and Wehner 1982, 1984). Discrepancies between the real azimuth of the feeder and the recalled azimuth communicated under test conditions led to the reconstruction of a proposed internal representation of the skylight polarization pattern in the brain of the bee. If the bee had comprehensive knowledge of the skylight polarization pattern, it would not make any errors under these testing conditions. As errors occur, the bee's internal representation of the sky must be a simplified version of the real world. The anatomical layout of the DRA (see below) was proposed to be the physical substrate of this representation and thus to act as a matched filter that could be aligned with the skylight polarization pattern (Wehner 1989). When this matched filter is rotated under the sky, temporal comparison of the pooled DRA output would be suited to identify the symmetry plane of the sky and thus allow to locate a specific azimuth relative to this symmetry plane. Due to the involved scanning behavior, this method was termed the

scanning hypothesis. Indeed, such behavior can be observed in desert ants intermittently throughout a foraging trip (Wehner 1989). Interestingly, some species of dung beetles also perform a rotational "dance" before choosing a movement direction (Baird et al. 2012). These insects use the polarization pattern of the sun or the moon to roll a freshly made dung ball in a straight line away from a dung pile in order to avoid competition. Overall, the scanning method is an elegant explanation to account for systematic errors present in the bee's navigational system and would enable the animal to obtain directional information in a very simple way. In principle, one neuron that encodes the pooled DRA output with its action potential frequency would be sufficient. Conclusive models that culminate in a hypothetical array of compass neurons have been based on elaborations of this theory (Wehner and Labhart 2006; Wehner 2001; Sakura et al. 2008) and await to be reconciled with the complex neurophysiological data from other insects (see below). Whether the ommatidial array of the DRA is indeed the physical substrate of a matched filter of the sky, or if such a filter is implemented in later stages of the brain, remains to be shown through neurophysiological studies. The complex system of polarization-sensitive neurons in the brains of other insect species, combined with the different shapes and ommatidial arrangement in the DRA across species (see below), however, leaves some doubt as to whether the scanning method is indeed implemented in such a straightforward way in all insects, despite the stunning elegance and simplicity of the proposed idea.

Detection of Polarized Light

In animal eyes, light is absorbed by rhodopsin molecules, which consist of a protein component (opsin) and the photosensitive molecule retinal. As retinal absorbs light preferentially if the plane of oscillation is aligned in parallel with the excitable double bond of the molecule, all rhodopsins are inherently sensitive to the *E*-vector orientation (plane of oscillation) of linearly polarized light (Fig. 1c). However, this only translates into

Polarization Vision, Fig. 3 The dorsal rim area (DRA) of insects is specialized for detecting polarized light. (a) DRA of the monarch butterfly. Shown is the distribution of microvilli orientations of the horizontal retinula cells (H), which results in a fanlike arrangement of preferred *E*-vectors along the length of the DRA. The inset depicts a single ommatidium with the characteristic two blocks of orthogonally oriented microvilli (Modified from Labhart et al. 2009). (b) Structure of the DRA of the desert locust.

Note that the DRA is much wider in the locust compared to the monarch butterfly and that in the monarch, horizontal ommatidial orientations dominate in the anterior and posterior parts of the DRA, while vertical orientations dominate in the medial part of the DRA. In the locust, all regions of the DRA comprise a wide variety of ommatidial orientations (Modified from Homberg and Paech 2002). (c) Estimated receptive fields of the right (yellow) and left (blue) DRA of the monarch butterfly projected onto a

polarization-sensitive photoreceptors, if the rhodopsin molecules are aligned in parallel to one another. Partially, such alignment automatically arises in all rhabdomeric photoreceptors of invertebrates, as the photopigments are embedded in the membranes of the microvilli, i.e., elongated, tubelike structures that protrude unilaterally from the cell body of the receptor cell (Fig. 1b; Horváth and Varjú 2004; Roberts et al. 2011). Even if rhodopsin molecules were randomly oriented within these membranes, the receptor would still be twice as sensitive to *E*-vectors oriented in parallel to the microvilli than to *E*-vectors perpendicular to them (i.e., it would have a polarization sensitivity (PS) of 2; Moody and Parriss 1961), provided that all microvilli of that receptor cell are themselves aligned in parallel to one another. As measured PS-values are much higher in the DRA of insects (up to 40 in crickets; Labhart et al. 1984), photopigments must be actively aligned within the microvilli membranes. Mechanisms of how such alignment could be achieved by tethering the components of the phototransduction pathway to elements of the cytoskeleton have been suggested but remain hypothetical (Roberts et al. 2011).

At the level of the ommatidia, i.e., the individual facets of an insect's compound eye, several mechanisms have been revealed that can increase (or actively reduce) the inherent polarization sensitivity of receptor cells. When detecting light, the animal is faced with the problem of having to identify whether a photoreceptor has absorbed many photons because the incoming light was very bright, of optimal spectral composition, or of optimal *E*-vector orientation. Eliminating polarization sensitivity is relatively easily achieved by twisting the photoreceptor (and the orientation of the microvilli) along the length axis

of the receptor cell (Wehner et al. 1975). A photoreceptor twist has indeed been observed in the retina of many insects and is thought to eliminate interference between color vision and (accidental) *E*-vector detection (Wehner and Bernard 1993). However, separating the *E*-vector information from spectral and intensity information cannot be achieved by one single receptor cell. To render the ommatidial output insensitive to spectral and intensity information and to enhance PS, a region of the insect compound eye has been dedicated to polarization vision, the dorsal rim area (DRA). Here, in each ommatidium, two groups of untwisted photoreceptors have evolved with microvilli orientations orthogonal to one another (Fig. 3a, b, insets; Labhart and Meyer 1999; Blum and Labhart 2000; Homberg and Paech 2002; Labhart et al. 2009). Additionally, both groups of photoreceptors express identical opsins, i.e., they possess the same spectral sensitivity (Labhart and Meyer 1999). In most insects, UV opsins are expressed in the DRA (flies (Wernet et al. 2003), monarch butterflies (Sauman et al. 2005; Stalleicken et al. 2006), bees (Labhart 1980), ants (Labhart 1986), dung beetles (Dacke et al. 2002)), while in locusts (Eggers et al. 1993) and crickets (Labhart et al. 1984; Henze et al. 2012), blue opsins carry out the task of perceiving polarized light. Green opsins have also been observed in the DRA of some insects (cockchafers, Labhart et al. 1992; dung beetles, Dacke et al. 2002). If the output of these orthogonal groups of receptors is subtracted from each other, the resulting information in the post-synaptic neuron will be independent of color and intensity, as both receptor groups are equally affected by changes of these parameters and only differ in their sensitivity to the *E*-vector orientation of the incoming light. Additionally, the

Polarization Vision, Fig. 3 (continued) zenithal view of the sky. (d) As (c), but for locusts and crickets. Note that the region of sky viewed by monarch butterflies on the one hand and locusts and crickets on the other hand is dictated by the anatomical layout of the DRA and thus differs substantially between the two groups. Long, elongated DRAs can be also found in flies, while broad, flat DRAs

are also found in cockchafers and dung beetles. Bees and ants appear to have DRAs with intermediate properties (C/D are based on data from Blum and Labhart 2000; Homberg and Paech 2002; Labhart et al. 2009; Stalleicken et al. 2006). *Abbreviations:* *V* vertical retinula cells, *D* diagonal retinula cells, *RCN* nucleus of retinula cell, numbers of retinula cells (photoreceptors R1–R8)

postsynaptic neuron would show a behavior called polarization opponency, as it is inhibited by one group of photoreceptors but excited by the second one. Although the anatomy of DRA ommatidia across insects strongly suggests such mechanisms, to date no electrophysiological recordings from their target cells in the lamina or medulla have been performed to directly prove this model.

The orthogonal blocks of untwisted microvilli described above are found in the DRA across insects. Additionally, many species possess other specializations that either enhance the sensitivity to polarized light or increase the overall sensitivity at the expense of spatial resolution (reviewed in Labhart and Meyer 1999). Examples of such specializations are shortened rhabdoms, which reduce the problem of self screening. Widened rhabdoms are also present in many species and result in increased sensitivity and sampling over larger visual angles, i.e., widened receptive fields. The lack of screening pigments in the DRA of some insects also dramatically increases the receptive fields of individual photoreceptors. In crickets, this results in receptive fields of ca. 20° (compared to 6° in the rest of the eye). Degraded optics and light-scattering devices in the optical path act as a low-pass filter for incoming light in the DRA of many insects and are thought to render these ommatidia insensitive to local variations in *E*-vector information, e.g., in partly cloudy skies.

The DRA as a whole exhibits further specializations, particularly suited for detecting the polarization pattern of the sky. All DRAs studied to date show a fanlike arrangement of ommatidial orientations (i.e., the orientation of their principal microvilli orientations) that enable the detection of all possible *E*-vectors within the DRA at any given time (Fig. 3a, b; Blum and Labhart 2000; Homberg and Paech 2002; Labhart et al. 1992, 2009). In principle, two types of DRAs exist. The first one is found, for example, in locusts and crickets and is characterized by a wide but short shape (Fig. 3b). The optical axes of its ommatidia are directed to the contralateral sky hemisphere and cover a large portion of the sky (Fig. 3d). The individual photoreceptors have large receptive

fields that overlap substantially between neighboring ommatidia (Blum and Labhart 2000; Homberg and Paech 2002). Due to the fanlike arrangement of preference angles, each region of the DRA is suited to detect all possible *E*-vectors. The second type of DRA is found, for example, in monarch butterflies (and in an even more extreme form in flies) (Fig. 3a). It is only very few rows of ommatidia wide but extends over a large range from posterior to anterior along the medial rim of the compound eye. Its ommatidia possess receptive fields generally not dramatically increased in size relative to the remainder of the eye. They are also directed contralaterally but only cover a narrow stripe of sky parallel to the body length axis of the animal (Fig. 3c; Labhart et al. 2009; Henze 2009). As the fanlike arrangement of the preference angles becomes stretched out along the DRA and individual ommatidia do not possess overlapping receptive fields, parts of the DRA directed towards the anterior sky are tuned to different *E*-vectors than parts of the DRA directed towards the zenith. This means that although both types of DRA are specialized for detecting the skylight polarization pattern, they transmit quite different information to the processing centers of the brain, even when facing identical skylight situations.

As mentioned earlier, polarized skylight is the major source of polarized light in nature, but not the only one. In animals using polarized light to detect water surfaces, ventral regions of the eye have evolved specializations similar to the DRA of other insects (e.g., in the back swimmer *Notonecta glauca*; Schwind 1983). Recently, data has accumulated suggesting that ventral polarization vision is more widespread than previously thought. Behavioral experiments in *Drosophila* have shown that ventrally presented polarized light is well suited to elicit orientation responses, which are likely mediated by a group of untwisted photoreceptors in the ventral retina (Wernet et al. 2011). Anatomical data from polarization-sensitive optic lobe neurons in the locust have revealed branching patterns that correlate with the location of the DRA as well as an unknown ventral eye region (el Jundi et al. 2011). At last, opsin expression studies in the cricket

show blue-sensitive opsins in the DRA and in a ventrally directed band of ommatidia (Henze et al. 2012).

Polarization vision in marine crustaceans, in particular stomatopods (mantis shrimp), has been extensively studied as well (Marshall and Cronin 2011). In these animals, ommatidia sensitive to linearly polarized light are present in the dorsal and ventral eye hemispheres. Additionally, two rows of ommatidia along the equator of the eye are suited to detect circularly polarized light, a feature so far unique in the animal world (Chiou et al. 2008; Kleinlogel and Marshall 2006; Marshall et al. 2007). These ommatidia use the rhabdom of one distal photoreceptor as quarter wave retarder within the light path of the remaining receptors. In this way, it transforms circularly polarized light into linearly polarized light that is in turn detectable by the crossed microvilli arrangement in the underlying receptor cells (Chiou et al. 2008).

Polarized-Light Processing in the Brain of Insects

Although most behavioral work in relation to polarized-light perception in the context of orientation and navigation has been carried out in honeybees and ants, virtually all knowledge about how this information is processed in the insect brain results from work in the desert locust, the field cricket, and the monarch butterfly (Merlin et al. 2012; Homberg et al. 2011; Labhart and Meyer 2002). In these species, intracellular recordings from anatomically identified neurons have been performed for over two decades, and over 30 types of neurons sensitive to polarized light have been identified. Together, they form a network, spanning almost all processing stages from the photoreceptors of the DRA to the neurons descending to the motor centers of the thorax.

To understand how this network processes information and transforms sensory input into motor commands that guide orientation behavior, one has to understand the physiological response characteristics of the involved neurons, their anatomical characteristics, and the neural connections

between the individual elements of the system. Much progress has been recently made in describing response characteristics of individual neurons of this “POL network,” as well as in understanding the detailed morphology of all major neuron types involved in processing polarized-light information. Although many neural connections are implied by the anatomical features of the involved neurons and are supported by indirect physiological data, very few neural connections have been verified in this network so far.

Individual neurons respond to different *E*-vectors with changes of their action potential frequency. When the animal is stimulated with a continuously rotating polarizer from the zenith, such neurons show approximately sinusoidal modulations of their mean firing rate (Fig. 4; Labhart 1988; Vitzthum et al. 2002; Heinze and Reppert 2011). Due to the axial symmetry of polarized light, two *E*-vectors elicit peak activity ($\Phi_{\max}$ -value) during each 360° rotation of the polarizer, with the peaks being separated by 180°. Minimal activity occurs at *E*-vectors orthogonal to $\Phi_{\max}$ ($\Phi_{\min}$ -value). The amplitude of modulation is a measure for the strength of the response. It can be quantified as a single number, the R-value. The larger this value, the stronger are the activity fluctuations during the rotation of the polarizer (Labhart 1996; Kinoshita et al. 2007; Heinze et al. 2009).

Depending on the relation of background firing rate and maximal and minimal activity during polarized-light stimulation, responses can be either purely excitatory (Fig. 4b), purely inhibitory, or both. The latter case, i.e., excitation near the $\Phi_{\max}$ -value and inhibition near the $\Phi_{\min}$ -value, is called polarization opponency and is a feature shared by many polarization-sensitive neurons in the brains of all examined insect species (Fig. 4a). Polarization opponency implies that at least one inhibitory neuron and one excitatory neuron with opposite *E*-vector tunings converge on the polarization opponent cell (Labhart 1988). Alternatively, polarization opponency can theoretically also be achieved by purely inhibitory input, if rebound excitation occurs between well-spaced bouts of inhibitory transmitter release events (Pfeiffer et al. 2011).

Polarization Vision, Fig. 4 Neuronal response to polarized light. When stimulated with a rotating polarizer from the zenith, the different E -vector angles elicit a sinusoidal change in spiking frequency. (a) The *top trace* shows the mean frequency (sliding average) of the spike train shown in the *lower trace*. Relative to its background firing rate (gray line in *top trace*), the depicted neuron of the anterior optic tubercle (TuTu1) from the locust is inhibited at the activity trough ($\Phi_{\min}$) and excited at peak activity ($\Phi_{\max}$),

i.e., it exhibits polarization opponency. The *blue bar* illustrated the presence of polarized light, while the *black ramp* illustrates the rotation of the polarizer. The *double arrows* indicate the E -vector orientation (Modified from Pfeiffer et al. 2005). (b) As (a), but for a LoTu1 neuron. This type of neuron does not show polarization opponency but is exclusively excited by all E -vector orientations (Data kind courtesy of B. el Jundi)

Optic Lobe

Beneath the retina of an insect compound eye lies a series of three retinotopically organized brain regions together referred to as the optic lobe. Located on either side of the central brain, they are the first processing stages of all visual information from the eyes. From distal to proximal,

these neuropil regions are called the lamina, the medulla, and the lobula complex. Dependent on the species, the lobula complex can consist of only one neuropil, of two neuropils (lobula and lobula plate), or of several neuropils (e.g., four in the locust) (Fig. 5a).

The axons of the photoreceptors from the DRA terminate in specialized dorsal rim areas of the

Polarization Vision, Fig. 5 Polarization vision pathway in the brain of the locust. (a) Schematic representation of polarization-sensitive neurons of the locust optic lobe. Photoreceptors from the dorsal rim area (DRA) of the compound eye terminate in the dorsal rim lamina (DRLa) and the dorsal rim medulla (DRMe). From there, a set of transmedulla neurons (TM) is proposed to transfer the information to the lobula and the anterior optic tubercle (AOTu). TM cells are suited to integrate input from the main retina (orange) as well. Several types of large, polarization-sensitive tangential neuron possess overlapping branches in the same layer as TM neurons, providing connections to the contralateral medulla (Me_c), the ipsilateral lamina (La) and medulla (Me), and the accessory medulla of both hemispheres (aMe , aMe_c). (Based on data from el Jundi et al. 2011). (b) Schematic overview of the locust brain with neuropils involved in processing polarized-light information highlighted in yellow. Input pathways are shown on the right side of the brain (as seen by the animal), while output pathways are shown

on the left side. Proposed pre- and postsynaptic endings of cells are indicated by filled circles and open half circles, respectively. (c) Schematic representation of the polarization vision pathway in the central brain of the locust, emphasizing all neurons associated with the AOTu. Neurons with proven bilateral input are highlighted in blue. Intertubercle neurons ($LoTu1$ and $TuTu1$) occur only once or twice per hemisphere, while $TuLAL$ neurons and tangential neurons of the central complex (TL) occur in many individuals. Neuron names are indicated by italic lettering. Abbreviations: LoX lobula complex, $AOTu-UU$ upper unit of the anterior optic tubercle, $AOTu-LU$ lower unit of the anterior optic tubercle, *ant. Lo* anterior lobula, LBU lateral bulb, MBU medial bulb, CX central complex, CBU upper division of the central body, CBL lower division of the central body, PB protocerebral bridge, LAL lateral accessory lobe, AL antennal lobe, MB mushroom body, $POTu$ posterior optic tubercle, pPC posterior protocerebrum, *ipsi* ipsilateral, *contra* contralateral. Italic abbreviations: names of neuron types

lamina and the medulla in the locust and cricket, while all receptors found to date in the monarch butterfly could be traced to the medulla (Sauman et al. 2005; Blum and Labhart 2000; Homberg and

Paech 2002). The neurons directly postsynaptic to the photoreceptors are unknown, but anatomical data from locusts and bumblebees suggests that transmedulla neurons arborizing in the dorsal rim

medulla and in one layer of the main medulla transfer information about polarized light to the lobula and further on to the central brain (Fig. 5a; Pfeiffer and Kinoshita 2012; Homberg et al. 2003). All physiologically characterized polarization-sensitive neurons of the optic lobe are tangential neurons with arborization trees covering large portions of the medulla. These cells are either restricted to one optic lobe or cross the midline of the brain and provide a substrate for information flow to the medulla of the contralateral hemisphere. Interestingly, all of these neuron types in the locust have branches restricted to the same layer of the medulla, suggesting that this layer is dedicated to processing polarized-light information (Fig. 5a; el Jundi et al. 2011).

All of the cells described above respond to stimulation with a rotating polarizer from the zenith with sinusoidal modulations of their firing frequency. In fact, the first polarization-sensitive neurons recorded from any insect brain belonged to a group of neurons connecting the medullae of both brain hemispheres in the optic lobes of the cricket (Labhart 1988). These so-called POL1 neurons have been extensively studied and are characterized by polarization opponency, large, contralaterally located receptive fields, and a tightly defined $\Phi_{\max}$ -value. Interestingly, when the population of POL1 neurons from one brain hemisphere is analyzed, three distinct tuning classes of these cells can be distinguished (with respect to the body length axis and plotted clockwise: 10° , 60° , and 130° for neurons with their soma located in the left brain hemisphere (Labhart et al. 2001)). The neurons of the contralateral hemisphere are tuned to mirror symmetrical $\Phi_{\max}$ -values. Therefore, three individual POL1 neurons likely exist in each optic lobe. These cells do not respond to unpolarized light but are extremely sensitive to polarized light down to intensities below that of a moonless night (Labhart et al. 2001). Additionally, the responses are robust even at degrees of polarization as low as 5% (Labhart 1996).

Aside from the cricket, polarization-sensitive neurons of the optic lobe have been also reported in the cockroach *Leucophaea maderae* (Loesel and Homberg 2001) and the ant *Cataglyphis*

(Labhart 2000) but have been studied in detail only in the desert locust (el Jundi et al. 2011; Homberg and Würden 1997; el Jundi and Homberg 2010). Here, five types of neurons have been described. Unlike in the cricket, most of the locust neurons (four out of five) do not show polarization opponency, but responses are purely excitatory. When stimulated from the zenith, all examined cells receive input from the ipsilateral eye only. The lateral extent of the receptive fields of three of the cell types has been described as well. In two cases (MeMe1 and TIM1 cells), it matches the data from the cricket. For one cell type (TML1 cell), however, the receptive field is located in the ipsilateral sky hemisphere. Together with the exclusively ipsilateral input, this suggests that this neuron type receives its polarized-light information from the main retina, as the ipsilateral DRA is directed towards the contralateral sky hemisphere (el Jundi et al. 2011). When the distributions of *E*-vector tunings are compared to the cricket POL1 data, no matching triple-peaked distribution exists for any of the examined locust neuron types. Nevertheless, the tunings of TIM1 and MeMe1 cells are each clustered around one single value, each of which approximately matches one of the three tuning classes described in the cricket (after values have been transformed to the cricket coordinate system: TIM1 = 67° and MeMe1 = 20°) (el Jundi et al. 2011). This suggests that there are differences in *E*-vector coding even between closely related species and that the tasks performed by one cell type in the cricket optic lobe might be distributed among several types of neuron in the locust.

At last, the cricket POL1 neurons as well as several of the described cell types of the locust possess processes in a small neuropil of the optic lobe called the accessory medulla (Fig. 5a; el Jundi et al. 2011; Homberg and Würden 1997; el Jundi and Homberg 2010; Labhart and Petzold 1993). As this neuropil has been implicated in a circadian function in several insect species (it is the seat of the internal clock in *Drosophila* and the cockroach), these neurons may provide an interface between circadian timing information and polarized-light-based compass information (Homberg et al. 2011).

Anterior Optic Tubercle

The first region of the central brain involved in the processing of polarized light is the anterior optic tubercle (AOTu). This neuropil exists in all insects studied and comprises either two subunits (one large and one small, e.g., in locusts; Homberg et al. 2003) or one large and several small subunits (e.g., in the monarch butterfly; Heinze and Reppert 2012). Polarization-sensitive neurons have so far been exclusively identified in the small subunits (Fig. 5b, c). Although not characterized physiologically, the combined population of transmedulla neurons (see above) likely provides polarization-sensitive input to the AOTu from the optic lobe. Within the AOTu, two classes of neurons have been shown to respond to polarized light: first, cell types connecting the AOTus of both brain hemispheres (intertubercle neurons) and, second, cell types that project from the AOTu to small neuropils called the bulbs (lateral bulb [formerly: lateral triangle] and medial bulb [formerly median olive] in locusts) (Fig. 5c). The latter provide the output of the AOTu. Intertubercle neurons (named LoTu1 and TuTu1) have been intensely studied in the locust (Kinoshita et al. 2007; Pfeiffer et al. 2005, 2011; Pfeiffer and Homberg 2007; el Jundi and Homberg 2012), while the output neurons (TuLAL1a/b) have been studied in the locust as well as the monarch butterfly (Heinze and Reppert 2011).

All of these neurons respond to rotating *E*-vectors with sinusoidal modulations of their spiking activity. While most cell types exhibit polarization opponency, responses of LoTu1 cells are exclusively excitatory (Pfeiffer et al. 2005). The *E*-vector tunings of LoTu1 neurons (one per hemisphere) and TuTu1 neurons (two per hemisphere) are fixed to specific values in each cell type. These values are mirror symmetrical with respect to the midline in neurons of the contralateral hemisphere. In TuLAL cells on the other hand, many different tunings occur both in the locust and in the monarch, suggesting that the population of these neurons (ca. 60 per hemisphere in the locust) could cover all possible *E*-vectors (Pfeiffer et al. 2005). Intertubercle

neurons receive input almost exclusively from the ipsilateral eye and possess relatively large receptive fields centered in the contralateral sky hemisphere at ca. 60° elevation, in tune with the orientation of the DRA (el Jundi and Homberg 2012). The receptive fields of TuLAL neurons are smaller and more variable between individual recordings. They are generally also directed contralaterally, indicating that each individual cell covers a small patch of sky viewed by the ipsilateral DRA. The tuning of each TuLAL cell would be expected to match the average microvilli orientation of the ommatidia converging on it. Although examined only in one recording, binocular input has been revealed in one TuLAL1a neuron of the locust, indicating interhemispheric information exchange already in early stages of the polarization vision pathway (Fig. 5c; el Jundi and Homberg 2012). As the described results were obtained in studies with laboratory-raised locusts, additional experiments were performed on locusts that had been raised with clear view of the sky. Surprisingly the distinct tunings of intertubercle cells are not present in those animals. Rather, all possible *E*-vector tunings occur across recordings. Interestingly, these values follow a predictable curve, when plotted against the time of day. This finding of the daytime-dependent adjustment of *E*-vector tunings of AOTu cells has been observed in locusts and monarch butterflies and is part of a mechanism referred to as elevation compensation (see below) (Heinze and Reppert 2011; Pfeiffer and Homberg 2007). This raises interesting questions about how the $\Phi_{\max}$ -values of these cells are generated and indicates that the polarization vision pathway is subject to experience dependent plasticity.

In the locust, these cells, in particular the two types of intertubercle neurons, have been also examined with respect to their responses to different intensities of polarized light, as well as to different degrees of polarization. TuLAL and TuTu neurons are largely intensity independent, i.e., they maintain their full response strength over several orders of magnitude of light intensities (Kinoshita et al. 2007; el Jundi and Homberg 2012). Below a threshold, the response quickly breaks down, leading to an all-or-nothing

response curve that is not suited to encode the stimulus intensity. Different from this behavior is the LoTu1 neuron, which shows a uniquely bell-shaped intensity-response curve. The rising slope is much shallower compared to the other cell types, indicating that *E*-vector responses of LoTu1 neurons are not intensity independent. Additionally, these cells are inhibited when stimulated with very bright polarized light (midday conditions). This suggests that these cells could play a role in adjusting the gain of the polarization vision channel in response to different illumination situations, e.g., shut down the system during midday when solar elevation is high and polarized-light information in the receptive field of the DRA is not reliable due to low degrees of polarization (el Jundi and Homberg 2012).

Interestingly, when stimulated with unpolarized light from the zenith, LoTu1 neurons are inhibited, while responses to rotating *E*-vectors from the same direction are purely excitatory (Pfeiffer et al. 2005, 2011). As unpolarized light is merely a blend of polarized light of all possible *E*-vector orientations, this behavior seems paradox. When the degree of polarization of the stimulation light was reduced from 100% to lower values and finally to unpolarized light, the purely excitatory response first turned into a polarization opponent response (containing excitation and inhibition), then to a purely inhibitory frequency modulation, and finally to near total inhibition. This means that the mean activity during the stimulation, as well as the response strength, was reduced when the degree of polarization was decreased. The reduced response strength can be intuitively explained by a more noisy input at lower degrees of polarization. To explain the reduced overall firing in the same situations, a model was developed, in which bouts of inhibitory transmitter release by photoreceptors lead to inhibition combined with rebound excitation in the postsynaptic cells (Pfeiffer et al. 2011).

Central Complex

The polarized-light information carried by the AOTu projection neurons (TuLAL neurons) is

directly transmitted to input neurons of the central complex (TL neurons). The synapses between these neurons are located in the bulbs, small neuropil regions with a characteristic microglomerular appearance. This organization results from highly specialized, very large synaptic complexes between the described cells (Träger et al. 2008). These remarkable synapses resemble similar structures in the auditory pathway of vertebrates that are essential for ensuring precise timing of action potentials when comparing signals originating from both ears. It has therefore been suggested that these synapses might play a similar role for accurately timing binocular integration of inputs from either eye in the polarization vision pathway of insects, e.g., to establish a robust estimate of body orientation during fast rotational movements of the animal. Although these synapses have not yet been studied physiologically, their conserved occurrence across many insects (e.g., locusts, monarch butterflies, flies, bees) suggests that they are essential for the processing of skylight compass cues before this information reaches the central complex (Pfeiffer and Kinoshita 2012; Träger et al. 2008; Heinze et al. 2013; Seelig and Jayaraman 2013).

The central complex is a midline spanning group of neuropils and consists of three major subunits: the protocerebral bridge (PB), the upper division of the central body (CBU; fan-shaped body in flies), and the lower division of the central body (CBL; ellipsoid body in flies). These regions are characterized by a regular neuroarchitecture of vertical columns (usually eight per hemisphere) and orthogonally intersecting layers (in the central body) (Fig. 6; Heinze and Reppert 2012; Heinze and Homberg 2008; Hanesch et al. 1989; Williams 1975; Lin et al. 2013). The layers are predominantly produced by neurons that connect external protocerebral regions with the central body. These so-called tangential neurons are thought to provide the major input to the central complex and occur in many different types in the CBU (Heinze et al. 2013; Hanesch et al. 1989; Young and Armstrong 2010). In the CBL, much fewer of these cells exist, which receive input almost exclusively from the bulbs and respond robustly

Polarization Vision, Fig. 6 Processing of polarized-light information in the central complex (CX) of the desert locust. The majority of cell types shown are also conserved in the monarch butterfly. From *top to bottom*, the input stage, the intermediate stage, and the output stage of the CX polarization-sensitive neuronal network are schematically illustrated. Note that only information reaching the CX from the left side is shown for simplicity. Two parallel pathways from the lower unit of the anterior optic tubercle (AOTu-LU) terminate in individual layers of the lower division of the central body (CBL) after passing through the lateral bulb (LBU) and medial bulb (MBU). CL1a neurons are suited to carry this information from the CBL to the contralateral hemisphere of the protocerebral bridge (PB). These neurons also provide a first output to an unnamed compartment of the lateral accessory lobe (LAL) near the LT (anterior loblet in the monarch butterfly). Within the PB, TB1 neurons are likely postsynaptic to CL1a cells and are suited to bilaterally integrate polarized-light information from both hemispheres. These cells provide output to one PB column in each hemisphere and additionally project to the posterior optic tubercle (POTu), where intertubercle neurons (*pTuTu*) potentially

provide a closed loop between TB1 neurons of both hemispheres. The *inset* on the *top right* illustrates the unique arborization pattern of TB1 neurons in the PB (Modified from Heinze and Homberg 2007). Each row represents an individual neuron, gray squares indicate columns filled with proposed input fibers, and black squares indicate columns filled with proposed output fibers. The potentially complex interplay of CL1a, TB1, and *pTuTu* neurons is likely involved in creating the systematic representation of zenithal *E*-vector tunings observed in TB1 cells (*double arrows*). TB1 cells likely possess inhibitory synapses onto CPU1 output neurons. These cells project from the PB to the contralateral LAL (ventral shell) and also comprise a systematic representation of *E*-vectors in the PB, which is out of phase with the TB1-representation by 90°. CPU1 cells additionally receive input from the upper division of the central body (CBU) and are thus suited to integrate behaviorally relevant aspects of the sensory world represented in the CBU with information about body orientation represented in the *E*-vector map of the PB. The asterisks highlight the converging output sites of the CX polarization-sensitive neuronal network

to zenithal polarized-light stimulation (Sakura et al. 2008; Vitzthum et al. 2002; Heinze and Reppert 2011). Detailed comparisons between the monarch butterfly and the desert locust have shown that this group of neurons is anatomically and functionally highly conserved and, together with TuLAL cells, constitutes two parallel, non-redundant input pathways from the AOTu to the CBL (Fig. 6, top; Heinze et al. 2013; Müller et al. 1997). Due to the large evolutionary distance between these species, this high degree of conservation is remarkable but is also reflected in the later stages of the polarization vision network. As the tangential neurons together are combined into the input stage of the central complex, the other polarization-sensitive neurons of the central complex have been grouped into an intermediate processing stage (CL1, TB1 neurons; Fig. 6 middle) and the proposed output stage (CPU1 neurons; Fig. 6 bottom), based on anatomical and physiological features of the cells.

The tangential neurons of the CBL likely pass their information to a specific set of columnar neurons (CL1). Columnar cells generally are the second major class of central-complex neurons. They possess small arborization trees (covering the width of one column) in the PB and connect these columns to corresponding regions of the CBU or the CBL, while additionally providing output axons to brain areas called the lateral accessory lobes (LAL), neuropils lying on either side of the central complex. Columnar neurons occur in isomorphic sets of 16 cells (one per column) and interconnect the PB and the central body via complex heterolateral projection schemes, suggesting complex patterns of interhemispheric information flow (Heinze et al. 2013; Heinze and Homberg 2008; Hanesch et al. 1989; Lin et al. 2013). The polarization-sensitive CL1 cells are conserved in all examined insects and occur in two subtypes, which, based on the anatomical distribution of proposed input and output fibers, provide a substrate for bidirectional information flow between columns of the CBL and the PB (Heinze et al. 2013; Hanesch et al. 1989; Heinze and Homberg 2009). In tangential input cells as well as in CL1 neurons, the *E*-vector tuning resulting from stimulation with rotating polarizers shown from the

zenith cannot be related to the cell's morphology. This is different in the neuron type presumably postsynaptic to CL1 cells. These neurons are multicolumnar cells of the PB (TB neurons) with a tangentially oriented main neurite spanning the length of the PB and, at least in locusts and monarchs, a connection to the posterior optic tubercle, a small neuropil at the back of the brain (Heinze et al. 2013; Lin et al. 2013; Heinze and Homberg 2007). Within the PB, proposed output fibers are present in two columns, one on either side of the midline at a distance of eight columns. The remaining columns are filled with proposed input fibers with the exception of the columns directly adjacent to the output domains, which remain empty (Fig. 6 middle). These neurons are therefore suited to integrate inputs from wide, bilateral areas of the PB and direct their output to two fixed columns on corresponding sites in either PB hemisphere. As these cells exist in an isomorphic set of eight individual neurons, the position of their output fibers can be correlated to physiological parameters of the neuronal responses. When this was done for the zenithal *E*-vector tuning of the neurons, it was revealed that each TB neuron is tuned to a specific *E*-vector angle according to its anatomical position along the PB. Moreover, this ordered array of tunings spans 180° per hemisphere, i.e., all possible *E*-vectors are represented exactly twice along the whole PB (Fig. 6; Heinze and Homberg 2007). As zenithal *E*-vectors are directly linked to the azimuth position of the sun, this array of neurons indirectly encodes the solar azimuth and is thus suited to act as an internal sun compass. Whether the double representation of 180° of zenithal *E*-vectors is a true representation of 360° of azimuthal space cannot be easily resolved by polarized-light stimulation alone, due to the inherent axial symmetry of *E*-vectors. However, data from the locust show that the *E*-vector tuning within the receptive fields of these cells is not constant but changes systematically in a way that could result in a matched filter for the polarization pattern of the sky (Heinze et al. 2009). The polarization pattern as a whole is therefore thought to elicit stronger responses in one half of the PB when the sun is in one sky hemisphere, while the

other half of the PB would respond stronger when the sun is in the opposite hemisphere, even though the *E*-vectors in the zenith are identical in both situations.

How this maplike representation of *E*-vectors is generated remains one of the major questions in the field. Likely, the complex interplay of CL1 neurons and TB1 neurons plays an important role, as both neuron types appear to be highly conserved across many insect species. Additionally in the locust, neurons that interconnect the posterior optic tubercles (el Jundi and Homberg 2010) have been suggested to provide a closed loop between TB1 neurons from both hemispheres and thus might be suited to refine or stabilize the *E*-vector map found in the PB (Fig. 6; U. Homberg, personal communication).

Most likely, TB neurons synapse onto several types of columnar neuron with input fibers in single columns of the PB (Heinze et al. 2013; Lin et al. 2013; Heinze and Homberg 2007). The most prominent example of such a neuron is a cell type called CPU1 neuron (Fig. 6 bottom). This cell type receives input not only from the PB but also from columnar domains within the CBU, while it provides output to large areas of the contralateral LAL. These neurons exhibit a strong correlation between their *E*-vector tuning and the position of their input arborization. As opposed to TB1 neurons, the systematic representation of *E*-vectors is shifted by 90°. This means that for a given column in the PB, the *E*-vector eliciting maximal excitation in TB1 neurons leads to minimal excitation (maximal inhibition) in the columnar neurons, suggesting an inhibitory connection between the two cell types (Fig. 6; Heinze and Homberg 2007).

Two additional potential output pathways for polarized-light information from the central complex exist. The first one has only been described in the locust and comprises two types of columnar PB cells projecting to small regions of the LAL close to the lateral and medial bulbs (Heinze and Homberg 2007, 2008). The second pathway involves the axonal projections of CL1 neurons to a different sub-compartment of the LAL (Fig. 6 middle). While this pathway is not very prominent in the locust, it is much more developed in the

monarch butterfly (larger axon diameters, wider projections fields, and more numerous terminals). Importantly, this pathway potentially bypasses the PB and could thus provide a direct link between the input neurons of the CBL and downstream targets in the LAL (Homberg et al. 2011; Heinze and Reppert 2011; Heinze et al. 2013; Heinze and Homberg 2009).

All of the described neurons respond to rotating *E*-vectors presented from the zenith with sinusoidal modulations of their action potential frequency. Despite the fact that these responses appear very similar, systematic differences between the physiology of neurons from different processing stages have been described (Heinze et al. 2009). In general, input stage neurons of the central complex have relatively small, contralaterally centered receptive fields, low background activity, low background variability, and high signal to noise ratios. The neurons of later processing stages, particularly the proposed output neurons, possess large, zenith-centered receptive fields and exhibit high background activity, high background variability, and lower signal to noise ratio. CL1 neurons, which have been proposed to link the input and output cells, show intermediate characteristics with respect to all of the described response features. These systematic changes in neuronal physiology suggest that input stage polarization-sensitive cells are specialized for this modality, while the output stage neurons are not maximally driven by polarized light alone and likely receive converging input from other sensory modalities (Heinze et al. 2009; Rosner and Homberg 2013). The proposed direction of information flow in output neurons has been further substantiated by direct observations of graded postsynaptic potentials only when these cells were recorded from the PB, while no such potentials were observed when the same cell types were recorded from their proposed output sites in the LAL (Heinze et al. 2009). The increasing size of the receptive fields suggests that neurons at later processing stages integrate signals from many input stage neurons with small receptive fields to eventually generate a position-invariant head direction signal that can be used to guide directed behavior.

At last, the complexity of the described polarization vision network of the central complex is further increased by the existence of neurons that respond to polarized light in a context-dependent way. These so-called conditional polarization-sensitive neurons have been described in the locust and comprise several types of columnar neurons with input in the PB and output projections to bilateral regions of the LAL or the contralateral nodulus (Heinze and Homberg 2009). In some recordings, these cells respond to polarized light similarly to all other described neurons, whereas in other recordings they remain unaffected by this stimulus, despite the fact that responses to unpolarized light in the frontal visual field remain present. Therefore, these cells appear to be recruited to the central-complex polarization vision network in a context-dependent way. The conditions that lead to this switch in response characteristics remain unknown. Also, whether similar neurons exist in other insects than the locust remains to be shown. However, as all the involved cell types have been described anatomically in many insect species, it seems not unlikely that the observed neuronal response characteristics could be a commonly shared feature across insects.

Beyond the Central Complex

The major output from the central-complex polarization vision network converges in a large region of the LALs defined by the target area of CPU1 neurons. In the locust, this region corresponds to the ventral shell of the LAL, while in the monarch butterfly it corresponds to the dorsal LAL (Heinze et al. 2013; Heinze and Homberg 2008). Polarization-sensitive neurons downstream of this area have been identified only in the desert locust. Two cell types are suited to integrate the converging output from the central complex with large input arborizations covering the whole projection area of CPU1 cells (Heinze and Homberg 2009). The first cell projects to the contralateral LAL, while the second type projects to large bilateral regions in the posterior protocerebrum, a region in which neurons descending from the

brain receive their input. As the latter neuron has been anatomically identified in the monarch butterfly as well, this neural pathway might be conserved in many insects (Heinze and Reppert 2011). Interestingly, neurons interconnecting the LALs of both brain hemispheres have been implicated in controlling steering movements during pheromone responses in moths (Iwano et al. 2010). One can speculate that similar cell types might also be involved in generating motor commands during behavioral responses to polarized-light stimulation (Merlin et al. 2012).

To induce behavioral responses of the animal, the polarized-light information has to reach the motor centers of the thorax. Indeed, such polarization-sensitive descending neurons have been identified in the locust (Träger and Homberg 2011). Two types of neuron possess their proposed input fibers in the posterior protocerebrum and descend either through the ipsilateral or the contralateral neck connective to target the subesophageal and thoracic ganglia. These cells respond to rotating polarized-light stimuli presented from the zenith with sinusoidal modulations of their firing frequency. These responses are considerably weaker and more variable compared to neurons from the central complex. However, this may be expected in cells separated from the sensory periphery by many synapses and suggests that they integrate many different sensory modalities. This is supported by strong, direction-dependent motion sensitivity in these neurons (Träger and Homberg 2011). Additionally, increased variability and lower signal to noise ratio were also observed in later processing stages of the central-complex polarization vision network (Heinze et al. 2009). Surprisingly, much stronger *E*-vector-dependent responses were observed in a type of neuron connecting the subesophageal ganglion to the prothoracic ganglion (Träger and Homberg 2011). Either these cells receive input from an unknown polarization-sensitive pathway or there is substantial local processing of information received from the known descending neurons within the ventral nerve cord that sharpens the tuning curves.

Overall, despite some gaps in understanding, combined data from the locust, the cricket, and the

monarch butterfly have led to the identification of a neural network involved in the processing of polarized light that spans most processing stages from the photoreceptors of the retina to neurons descending to the motor centers of the thorax. The significant challenge lying ahead is to verify the proposed links between these neural elements in order to combine them to a comprehensive network that performs the computations needed to explain an animal's behavior in response to polarized-light stimuli.

Integration of Polarized Light and Unpolarized Light

Polarized light is not the only orientation-relevant skylight compass cue. In fact, the sun itself is the most prominent feature of the sky and is indeed the primary source of information used for navigation, e.g., in the monarch butterfly (Reppert et al. 2004, 2010; Stalleicken et al. 2005; Froy et al. 2003). For choosing a reliable direction of travel, only the solar azimuth, i.e., the horizontal position of the sun, but not the solar elevation contains useful information. As the sun is often obscured behind clouds or other features of the visual scene, it is highly desirable for a navigating animal to extract the information about solar azimuth from indirect skylight cues, i.e., the skylight polarization pattern, the skylight spectral gradient, and the intensity gradient of the sky. The nervous system is thus faced with the challenge of integrating all these cues and combining them into a consistent representation of solar azimuth. By using more than one cue, the internal compass is expected to become more reliable and less prone to noise and interference in any of the individual channels.

The finding that polarization-sensitive neurons of the insect brain also respond to unpolarized light suggests that indeed information from other skylight cues is processed by the same neural substrate. The stimulus used most extensively is an unpolarized-light spot that is moved around the animal at a constant elevation of 30–45° (el Jundi et al. 2011; Heinze and Reppert 2011; Pfeiffer and Homberg 2007). This stimulus was applied in

recordings from locusts and monarch butterflies and was shown across different colors, ranging from ultraviolet to green. In principle, many polarization-sensitive neurons were maximally excited when the light spot passed through a specific azimuth value, while the light spot led to an inhibition of the spiking rate or to no response when it was present in the opposite direction (Fig. 7a, b). The resulting tuning curve with respect to the azimuth position of the stimulus is referred to as azimuth tuning of the cell.

When following the polarized-light information through the locust brain, unpolarized light is integrated with polarized light already in neurons of the optic lobe. Virtually all neurons with a defined $\Phi_{\max}$ -value for *E*-vectors also possess a reliable azimuth tuning (el Jundi et al. 2011). This tuning is independent of the color of the stimulus, so that green and UV stimulations result in identical or very similar tunings. This suggests that these cells encode the azimuth of the brightest point in the sky, i.e., the sun. Although it remains unknown where this information about solar azimuth is combined with information from the DRA, likely candidate cells have been anatomically described in the locust and in the bumblebee (el Jundi et al. 2011; Pfeiffer and Kinoshita 2012; Homberg et al. 2003). These transmedulla neurons possess input fibers in the dorsal rim of the medulla and additionally have one long input neurite passing vertically through the medulla, potentially enabling these cells to integrate information from all ommatidia that face one particular azimuth.

The population of the recorded optic lobe neurons showed that these cells exhibit fixed *E*-vector tunings that depend on the cell type. With respect to the azimuth tuning, the situation is more complex. Here, locusts that had been raised in the laboratory with no view of the sky possessed neurons with random azimuth tunings, while neurons from locusts that had been raised with a clear view of the sky showed identical tuning across all cells (tuned to the ipsilateral side, 90°) (el Jundi et al. 2011). This finding reveals that the tunings of these cell types are not static but rather depend on the experience of the animal. It also poses the question as to how both sources of information are

Polarization Vision, Fig. 7 Integration of polarized and unpolarized-light stimuli in neurons of the locust and the monarch butterfly. (a) Neuronal response of a neuron of the anterior optic tubercle (AOTu) of the locust to an unpolarized-light spot moving around the animal at constant elevation (45°). *Left*, green light; *right*, ultraviolet (UV) light. Shown are *circular plots* of mean spiking activity (bin size 20°) against the azimuth position of the stimulus. The *red line* indicates the background activity of the neuron (Modified from Pfeiffer and Homberg 2007). (b) As A, but for an AOTu neuron of the monarch butterfly. Other than in the locust, the neuron is tuned to identical azimuth values for green and UV light (Modified from Heinze and Reppert 2011). (c) Schematic representation of the skylight polarization pattern emphasizing the relation of *E*-vectors outside the zenith and solar azimuth at different solar elevations. *Top*: when the sun is close to the horizon, all *E*-vectors in the sky are oriented approximately in parallel, leading to a 90° relation between the solar azimuth and all *E*-vectors in the sky. *Bottom*: at higher solar elevations, this 90° relation is only given along the solar meridian (including the zenith (*z*), *violet*). Outside the solar meridian (*red*), assuming such a 90° relation leads to a significant error (*double arrow*), as the angle between the solar azimuth and the *E*-vector becomes smaller with increasing solar elevation (i.e., during midday) (Reprinted from Heinze and Reppert 2011). (d) *E*-vector

tuning and azimuth tuning to unpolarized-light spots moving around the animal for an AOTu neuron of the locust (*top*) and the monarch butterfly (*bottom*). The absolute difference between the green azimuth tuning and the *E*-vector tuning is defined as $\Delta\Phi_{\max}$ -value in locusts, while the difference between the *E*-vector tuning and the mean azimuth tuning to all tested colors is defined as the $\Delta\Phi_{\max}$ -value in the monarch butterfly (Modified from Merlin et al. 2012). (e) *Top*: $\Delta\Phi_{\max}$ -values of AOTu neurons plotted against the time of recording (bins of 72°) in the locust. The numbers in the bars represent the number of recorded neurons included in each bin. The data are fitted with a function (*red*) that describes the angular difference between solar azimuth and *E*-vector orientation for individual points of the sky over the course of the day. The fit is calculated for August 1 (within the rearing period of the used animals) and 60° elevation above the horizon according to the optical axis of the DRA. The fit line is calculated for the coordinates of the Tropic of Cancer (23.4°N), which lies in the natural habitat of the locusts. *Bottom*: As the *top* panel, but data for neurons recorded from the bulbs of the monarch butterfly (AOTu neurons and TL neurons) and plotted against zeitgeber time (0 = lights on [=sunrise]). The line represents the mean perceived *E*-vector in the region of sky viewed by the dorsal rim of the monarch over the course of the day, calculated for the location and date of capture of the used animals.

integrated into a consistent representation of solar azimuth.

Similar results have also been obtained from the monarch butterfly in neurons of the AOTu and tangential neurons of the CBL. These cells are tuned to an identical azimuth value of unpolarized green, blue, and UV light, located on the contralateral side of the animal (270° azimuth) for all recorded neurons (Fig. 7b; Heinze and Reppert 2011).

In the locust, neurons of the AOTu exhibit a different behavior. These cells are excited by green light from one direction, while they are inhibited by UV light at that azimuth (Fig. 7a). This color opponency is not suited to encode the brightest spot of the sky but rather the skylight spectral gradient (Kinoshita et al. 2007; Pfeiffer and Homberg 2007). Across the sky, the ratio of green light to UV light varies systematically and is defined by the angular distance of the observed spot of sky to the sun. In short, the closer a spot of sky is towards the sun, the more long wavelength light is present in the light received from that spot. The color opponent neurons of the locust polarization vision pathway consequently would be activated when the locust faces the solar hemisphere (given the preferred azimuth of the cell lies ahead of the animal), while it would be inhibited when facing the antisolar hemisphere. As the zenithal *E*-vectors are identical in both situations, this mechanism could be used to resolve the inherent ambiguity in the polarized-light signal resulting from the axial symmetry of *E*-vectors. How these response properties emerge from the potentially presynaptic optic lobe neurons without color opponency remains unknown.

Despite the differences between the monarch butterfly and the locust in the response characteristics of AOTu neurons (solar azimuth tuning

vs. spectral gradient encoding), both species share a remarkable aspect of their neural responses. In the described neurons, the *E*-vector tuning is adjusted with respect to the azimuth tuning of the same cell in a daytime-dependent way (Heinze and Reppert 2011; Pfeiffer and Homberg 2007). Given that polarized light was always shown from the zenith in these experiments, combined with the fact that zenithal *E*-vectors of the sky are always perpendicular to the solar azimuth, one would expect a fixed 90° relation between *E*-vector tuning and azimuth tuning of a particular neuron (Fig. 7c). However, when one analyzes the population of neurons in both the monarch butterfly and the locust, all possible difference angles between *E*-vector tuning and azimuth tuning can be observed. Plotted against the time of day, the data reveals that large values (close to 90°) are only found in the morning and evening, while small values are found during midday (Fig. 7e). This surprising behavior can be explained by considering that the DRA of the animals does not look exclusively into the zenith. The relation between *E*-vectors and the solar azimuth outside the zenith depends strongly on the solar elevation, which itself is a function of the time of day (Fig. 7c). Modeling of skylight parameters has shown that the angular distance between the mean perceived *E*-vector across the DRA of the monarch butterfly and the solar azimuth precisely matches the measured difference angles of the recorded neurons across the day, particularly when the place and time of capture of the animals is taken into account (Heinze and Reppert 2011) (Fig. 7e bottom). Similarly in the locust, fitting the recorded difference angles to a function that describes this parameter in the sky leads to the closest fit for the point of sky in the center of the locust DRA, especially when

Polarization Vision, Fig. 7 (continued) Data are binned in 1 h bins. Note that in both species, the angular difference between azimuth and *E*-vector tuning is large in the evening and mornings (at *low* solar elevations) and small around noon (at *high* solar elevations). Thus, the *E*-vector

tuning of the neurons changes over the course of the day to match the skylight situation in the region of sky viewed by each species' dorsal rim area, a process called elevation compensation (Modified from Merlin et al. 2012)

skylight parameters from the natural habitat of the locust were used (Pfeiffer and Homberg 2007) (Fig. 7e top). These findings highlight that the integration of unpolarized and polarized skylight cues is achieved by adjusting the *E*-vector tuning over the course of the day so that it always encodes the identical solar azimuth value that is also encoded by the information obtained from viewing the sun directly. This process is referred to as elevation compensation and leads to a consistent representation of the solar azimuth in both species at the input stage to the central complex, despite the fact that the information reaching the brain is strongly dependent on the different layout of the DRA.

Within the central complex, responses to the azimuth of unpolarized light have been reported in the monarch butterfly and are comparable to early stage neurons of the AOTu (Heinze and Reppert 2011). Due to the limited number of recordings, no information about the systematic representation of azimuth tunings exists for this brain region. Additionally, many types of polarization-sensitive neurons of the central complex in the locust have recently been shown to exhibit sensitivity to looming objects and to small moving objects, suggesting that integration of behaviorally relevant object information is integrated with compass information in these cells (Rosner and Homberg 2013).

Surprisingly, in the cricket no responses to unpolarized light in polarization-sensitive neurons have been revealed to date. However, no systematic analysis of azimuth-dependent responses has been carried out, so that the possibility of similar neural mechanisms for integrating solar azimuth and celestial *E*-vectors remains open.

Polarized Light as Global Frame of Reference for Insect Orientation?

Two of the three species studied most extensively with respect to the neural basis of polarized-light vision are long-distance migratory insects (desert locust, monarch butterfly), while the third (field cricket) is a central place forager. As most aspects

of the neural network that have so far been described appear to be highly conserved between even not closely related insect species, polarized-light vision is likely a fundamental feature of the navigation system of insects with highly developed orientation behavior.

However, skylight compass cues like polarized light all by themselves do not provide the animal with any useful information, as long as they are not combined with features of the environment that are either attractive or repulsive, i.e., need to be approached (e.g., food, mating partners, nest) or avoided (e.g., predators). Additionally, whether features are attractive or repulsive depends on the behavioral context. For example, the nest of a central place forager is only attractive on the inbound journey after a foraging trip. Hence, modulating factors, like the motivational state of the animal or the current time of day, have to be integrated when transforming sensory signals into motor commands. An animal constantly has to evaluate whether its current heading matches its desired direction of movement and translate any discrepancy into compensatory movements. If the behavior of the animal contains prolonged straight segments or involves a central point to which it has to return, a global frame of reference is of great value for ensuring accuracy (Lambert et al. 2011). It is in this context in which the sun and other celestial features (e.g., polarized skylight) can provide most valuable orientation cues.

The described neurons that encode both unpolarized and polarized skylight cues are not suited to mediate perception of either individual cue but are much more suited to encode body orientation with respect to the solar azimuth. In the later processing stages of the central complex, this information is then used to generate an ordered representation of azimuthal space, for which polarized skylight is likely only one of many contributing factors. One might speculate that this azimuth representation provides the frame of reference in which behaviorally relevant features of the environment are associated with directional information. This process of combining a “where” pathway (azimuth representation) with a “what” pathway (behaviorally relevant aspects of the sensory world) could provide the basis for generating

motor commands within the computational network of the insect central complex. With its exceptionally rich supply of neuromodulatory substances (Nässel and Homberg 2006; Kahsai and Winther 2011), the central complex is also a promising region for integrating the animal's motivational state necessary for generating appropriate behavior.

Polarization Vision Beyond Arthropods?

Given the substantial progress in understanding the neural mechanisms involved in polarized-light vision in arthropods, especially in insects, the question arises as to what is known about polarization vision in other animals. With regard to other invertebrates, polarization vision is well studied in cephalopods, such as squids, cuttlefish, and octopus (Horváth and Varjú 2004). Like in arthropods, the retina of the cephalopod's camera-type eye contains orthogonally arranged blocks of highly aligned microvilli, which theoretically allow intensity-independent encoding of *E*-vector orientations of polarized light, if polarization opponent processing occurs further downstream (Shashar et al. 2002). Behaviorally, these animals have been shown to use polarized light for intra-specific communication and prey detection and to mediate escape responses (Pignatelli et al. 2011). However, despite electrophysiological recordings from photoreceptors, virtually nothing is known about the neural basis of these behaviors.

In vertebrates, there is behavioral evidence for polarization sensitivity from all taxa, i.e., fish, reptilians, amphibians, birds, and mammals (reviewed in (Horváth and Varjú 2004)). Most systematically studied have been innate and conditioned orientation responses in fishes (Hawryshyn 2010), while recent work in birds has uncovered an important role of polarized light in calibrating the magnetic compass (Muheim 2011). Unlike invertebrates, vertebrates detect light with ciliary photoreceptors that do not contain microvilli. Rather, they are composed of stacks of radially symmetrical disks, in which rhodopsin pigments can rotate freely. Thus, unlike microvilli-based (rhabdomeric) photoreceptors,

ciliary photoreceptors are not intrinsically sensitive to polarized light. This requires intricate specializations of these receptors if polarization sensitivity is to be achieved. In fishes and birds, the so-called double cones have been implicated in mediating polarization vision. These receptors consist of pairs of cones tightly associated with one another. In salmonid fishes, the membrane separating the two cones is tilted at the apical end of their inner segments. This tilted membrane has been suggested to serve as a dichroic mirror that reflects light onto neighboring cones, which are hence illuminated transversely, not axially. At transverse illumination, the receptors are highly sensitive to *E*-vectors oscillating in parallel to the diameter of the disks, whereas they cannot be excited by orthogonally oriented *E*-vectors (Horváth and Varjú 2004; Hawryshyn 2010). Additionally, individual cones of the gold fish have been shown to exhibit weak polarization sensitivity even under axial illumination, albeit through an unknown mechanism (Roberts and Needham 2007). These receptors could thus mediate polarization sensitivity without the involvement of double cones. In birds, reflections in oil droplets in double cones have been proposed to serve a similar role in reflecting incoming axial light from the main cone onto its accessory cone and hence provide transverse illumination suited for *E*-vector detection (Muheim 2011). In reptiles and amphibians, polarization sensitivity has been revealed in several species by behavioral experiments (Horváth and Varjú 2004). Other than in birds and fishes, the retinal photoreceptors of the eyes are likely not involved in mediating this task. Indeed, extraocular photoreceptors in the pineal organ have been shown to be required for *E*-vector-dependent orientation responses (Beltrami et al. 2010). Finally, humans can be trained to perceive a visual effect induced by linearly polarized light, the Haidinger brush. This effect comprises *E*-vector-dependent color perception via an unknown retinal mechanism and suggests that polarization vision is also possible among mammals (Horváth and Varjú 2004).

Overall, compared to invertebrates, the field of polarization vision remains in its infancy in vertebrates. However, as the principles of how

E-vectors might be detected in the different vertebrate orders become increasingly well understood, the neural principles underlying polarized-light-induced behaviors may be elucidated in the not too distant future in at least some of the studied species.

Definition

Modeling of polypeptides and proteins, often referred to as biomolecular or molecular modeling, encompasses the use of theoretical models and computational methods to model the structure and dynamics of molecules of biological interest such as peptides, proteins and small organic molecules (ligands).

The aims of protein and peptide modeling for drug design include: (i) modeling the three-dimensional structure of proteins of current or potential drug targets; (ii) identifying and characterizing the structural dynamics associated with the function of a particular protein or peptide; and (iii) predicting the structure and molecular interactions of protein-ligand complexes. This knowledge underpins structure-based and rational drug design. It can aid in the design and optimization of drug molecules by shedding light on their mode of action, specificity and selectivity.

Detailed Description

Background

The number of protein structures solved experimentally and deposited in the Protein Data Bank (PDB) has risen exponentially since its inception in the 1970s (RSCB Protein Data Bank [2013](#)). This has been accompanied by a rapid growth in computational power and continuous improvements in modeling algorithms, greatly enhancing the complexity, size and diversity of the proteins that can be simulated. Together, the experimental and computational breakthroughs initiated in the 1970s have contributed enormously to our knowledge of protein structure and structural conservation within protein superfamilies. In 2013, the contribution of computational modeling to our understanding of protein structure and biochemical function was recognized by the award of the Nobel Prize in Chemistry to three of the founders of the field, Martin Karplus et al. (2013). Computational modeling techniques lie at the core of fields such as protein folding and dynamics, structure-based drug design and computer-aided drug design.

The majority of drugs targeting the central nervous system modulate the action of one or more neurotransmitters involved in synaptic transmission. Thus the most common drug targets fall into the category of cell surface receptors, such as metabotropic and G-coupled protein receptors (GPCRs), transporters and ion channels (Cross and Yocca [2012](#); Hefti [2004](#); Squire et al. [2008](#)). In fact, drugs targeting GPCRs account for over 50 % of all clinical drugs (Schushan and Ben-Tal [2010](#)). Despite their clinical significance, solving the experimental structure of transmembrane proteins remains challenging. In 2013, the PDB contained >94,500 structures, of which only 1954 are transmembrane proteins (RSCB Protein Data Bank [2013](#); Kozma et al. [2013](#)). This gap between the availability of structural models and the need for high-resolution structures of membrane proteins is a major obstacle in the design of drugs targeted for a specific protein or protein isoform. In many cases, both the protein dynamics and the precise details of the drug binding site is unknown. This makes it difficult to identify the

molecular interactions that govern the specificity of the drug. Furthermore, the existence of multiple subtypes or isoforms of many of these proteins, each with distinct physiologic functions, makes isoform selectivity crucial for drug efficacy. Computational modeling techniques offer a means to understand structure-function relationships of these critical proteins.

The Underlying Principles Behind Protein and Peptide Modeling Techniques

Computational modeling is used to address a myriad of question relevant to drug design. Examples include: predicting the structure of a protein from its amino acid sequence or from the structures of homologues; elucidating the relationship between protein structure and biological function; understanding how protein motion is associated with drug binding; determining the molecular basis of the drug-protein interactions that govern drug selectivity and potency; and understanding how drug binding modulates protein function. The most suitable modeling approach for a particular problem depends on the level of structural and biochemical information available and the question to be addressed. Figure 1 gives an overview of commonly used techniques that will be discussed here.

Simulation techniques for the modeling of proteins, peptides and drugs can be classified into three broad categories based on the underlying theory or principle: knowledge or rule based methods; potential energy methods; and quantum mechanical methods (Goodfellow 2008). More recent approaches combine two or more of these categories to improve the quality of the models obtained (Goodfellow 2008). For example, computational approaches that investigate protein dynamics, or protein–ligand interactions (such as molecular dynamics and docking techniques) are primarily based on potential energy methods, while structure prediction methods often combine an initial knowledge-based method with a potential energy method to further refine the model. Methods based on a purely quantum mechanical

approach are not feasible for molecules of more than 50 atoms due to current computational limitations. As most proteins and peptides are larger than this, quantum mechanical approaches will not be discussed here.

Knowledge Based Methods

Knowledge based methods for protein and peptide modeling use comparative statistical analysis to predict the structure of the amino acid sequence of the target protein from (i) the sequence of homologous proteins of known structure; or (ii) a database of protein structures (Rangwala 2010). The accuracy of this approach relies on the current knowledge of protein structures and the evolutionary relationship between the proteins.

Potential Energy Methods

Potential energy (PE) methods, are based on (i) a description of the fundamental parts of the system (usually atoms), (ii) a mathematical description of the interactions between the atoms; (iii) a starting configuration such as the coordinates of each atom in the system; and (iv) an algorithm to carry out the desired computational steps by evolving the system in time and space (Goodfellow 2008; Jensen 2007).

Most PE methods used for modeling polypeptides and proteins utilize a so-called molecular mechanics (MM) approach in which a system is described as a collection of spheres (representing one or more atoms), connected by bonds in the form of harmonic springs. Both the bonded and non-bonded interactions between all pairs of atoms are described by simple mathematical expressions, referred to as the forcefield, the general form of which is described in Eq. 1:

$$E_{\text{total}} = E_{\text{bond}} + E_{\text{angle}} + E_{\text{dihedral}} + E_{\text{electrostatic}} + E_{\text{vanderWall}} \quad (1)$$

where E is the potential energy. The underlying principle of MM assumes that the potential energy of the molecular system can be described as a function of the atom's position in space. The forcefield allows the change of energy in the system to be calculated as the atomic positions

Polypeptide and Protein Modeling for Drug Design, Fig. 1 An overview of the main techniques used to model proteins and peptides for drug design. The main aims of these techniques is to (i) model the three-dimensional structure of proteins of current or potential drug targets; (ii) identifying and characterizing the structural dynamics associated with the function of a particular protein or peptide; and (iii) predicting the structure and molecular interactions of protein-ligand complexes. In the absence of an experimentally determined protein structure,

homology modeling techniques can be used to predict the structure of a given protein from the sequence similarity to homologues of known structure. Docking simulations can be used to predict the interaction of drugs, ligands or other proteins with the protein of interest. From a high-resolution experimentally determined protein structure, the conformational dynamics within the protein and dynamic binding of drug molecules can be elucidated using molecular dynamics simulation techniques

P

change. The conformation of a protein or peptide is optimized with respect to its energy, as the assumption of the potential energy concept is that the minimization of the potential energy will give the optimal geometry of the protein or ligand. MM becomes particularly powerful when combined with algorithms that propagate the system in time or space (Jensen 2007; Náray-Szabó et al. 2012; Nowak 2012). These algorithms either propagate possible conformations of the protein to sample its conformational space, or examine how the system evolves over time.

Energy minimization and Monte Carlo algorithms are used to propagate the system in conformational space. Energy minimization algorithms (also referred to as geometry or energy optimization) calculate the gradient of the potential energy and evolve the protein in the direction of the minimum potential energy. Monte Carlo algorithms (named after the Monte Carlo casino) rely on repeated random sampling of an initial amino acid conformation to find the statistically most probable end state for the given initial conditions. These algorithms are particularly important for

finding stable, minimum energy conformations of a protein, for example, the local and global energy minima in protein folding or ligand binding pathways. They cannot give information about the timescales of these processes.

Langevin (or stochastic) dynamics and molecular dynamics use algorithms to examine the time-evolution of the system, but differ in the underlying equation of motion. Molecular dynamics is based on Newton's equation of motion:

$$m_i a_i = F_i(r) \quad (2)$$

where m_i , a_i and $F_i(r)$ are the mass, acceleration and force on the i th atom. Stochastic dynamics is based on the Langevin equation:

$$m_i a_i = F_i(r) - m_i \gamma_i(t) + \eta_i(t) \quad (3)$$

where the additional terms, $m_i \gamma_i(t)$ and $\eta_i(t)$ are the random force and frictional force on the i th atom that arise from molecular collisions due to the thermal motion of the atoms. By incorporating these forces, Langevin dynamics model the effects of water and other solvents without including them explicitly in the simulations. In contrast to algorithms that propagate the protein system in conformational space, algorithms that give the time evolution of the system provide information about the dynamics of the system and the timescale at which these occur. One of the major limitations of these algorithms is they often evolve to a local energy minima which is stable over the timescale (ns to μ s) of the simulation. Because of this limitation, time-evolution algorithms cannot currently sample the entire range of conformations that a protein system will adopt in a physiological environment.

Protein Structure Prediction

Homology Modeling

Proteins derived from a common ancestor are homologues and display a conserved amino acid sequence and three-dimensional structure. The extent of the sequence and structural conservation depends on the evolutionary distance

between the homologues. Homology or comparative modeling exploits these similarities to construct a structural model of the target protein based on the experimental structure of one or more homologues, referred to as the modeling template or templates. Conservation of protein folds between homologues guides the modeling, which follows four steps: fold recognition and template selection; target-template alignment; model building; and model assessment (Zvelebil and Baum 2008).

The reliability of the homology model is critically dependent on the accuracy of the sequence alignment between the homologues, and the resolution of the experimental structure of the homologue used as the modeling template. Single residue shifts in the alignment of the sequences can result in register shifts across large regions of the protein, seriously affecting the predictions of binding site residues and ligand coordination (Náray-Szabó et al. 2012; Zvelebil and Baum 2008). This is particularly relevant for the structure of transmembrane proteins such as channels, transporters and receptors. The general role of these proteins is to selectively allow the passage of a hydrophilic or charged moiety across a hydrophobic lipid bilayer. To facilitate this process, transmembrane proteins possess highly ordered secondary structures in which the exterior of the protein is a hydrophobic shell that shields a substrate-selective hydrophilic core from the lipid environment. Most channels and membrane transport proteins are composed of interacting α -helices. Here a residue shift of a single amino acid in one helix may alter the prediction of the entire interaction interface between two or more helices, and shift the orientation of binding site residues within an α -helix by 100° .

The sequence identity between the target and template proteins gives a limit to the confidence placed on the homology of the two proteins. 90 % of the proteins with sequence identities of >30 % are structural homologues, while for pairs of proteins with sequence identities of <20 %, less than 10 % were structural homologues (Rost 1999; Zvelebil and Baum 2008). Aligned proteins with sequence identities ranging from 30 % to 20 % represent the transition zone from a

high-confidence prediction of homology to a low-confidence prediction. This region is referred to as the “twilight zone” for homology modeling (Rost 1999). It should be noted that in transmembrane proteins, substitutions between hydrophobic residues are generally well tolerated, while the amino acid composition of the substrate-selective regions of the protein are tuned for the substrate of interest. For this reason, transmembrane proteins from the same family or superfamily often have sequence identities that lie within this twilight zone, increasing the possibility of alignment errors in homology modeling.

Modeling by Fold Recognition

In many cases, the three-dimensional structure of a protein is more highly conserved than the amino acid sequence. Threading or fold recognition approaches attempt to find a conserved structure that is compatible with the sequence of the target protein. The target sequence is “threaded” onto each protein in a database of experimentally determined protein structures and a scoring function is used to determine which structure best accommodates the target sequence. A high score indicates the structure is compatible with the target sequence and it is assumed that the target

sequence folds in the same manner (Zvelebil and Baum 2008).

Probabilistic Modeling of Protein Interactions

Molecular Docking Techniques

In the case of drug–protein, peptide–protein or protein–protein interactions, computational docking approaches predict an interaction interface between the protein and ligand, which may represent a stable binding mode. Molecular docking essentially involves two steps: (i) generation of a large number of possible configurations of the protein–ligand complex (binding poses); and (ii) scoring of configurations with the aim to distinguish possible protein–ligand configurations from those not physically possible (Xu et al. 2007). A set of example results from a docking simulation is shown in Fig. 2.

Docking methods vary significantly in the degree to which they account for the flexibility of the protein and the ligand. The majority of docking algorithms implement a rigid body approach, in which the internal flexibility of both the protein and the ligand is not considered.

Polypeptide and Protein Modeling for Drug Design, Fig. 2 Molecular docking conformations of protein–protein and protein–ligand docking simulations. Multiple poses of (a) a pseudokinase domain (colored from orange to red) docked onto a kinase domain (blue); and (b) an

inhibitor molecule (CPK coloring, *licorice*) docked onto a homology model of a human homologue of LeuT (grey ribbons). Note the extended loops in the model correspond to amino acid insertions not present in the LeuT crystal structure

More sophisticated approaches allow flexibility of the protein side chain or backbone atoms. The choice of method is essentially a trade-off between accuracy and speed. Rigid body methods are fast and robust and can be applied for virtual screening of a large number of potential ligands, albeit at low accuracy. More sophisticated flexible docking methods allow optimization of the protein-ligand complex. These methods are much slower, but provide greater accuracy (Xu et al. 2007). Recent data driven approaches use experimental information such as NMR chemical shift perturbation or mutagenesis data as internal constraints to drive the docking algorithm (Xu et al. 2007).

Scoring Functions are Used to Assess the Quality of Modeled Structures and Interactions

Scoring functions are an important concept used for assessing the quality of structural models predicted by either potential energy or knowledge-based methods. Scoring functions are approximate mathematical methods that give an empirical score that represents the mathematical quality of the model. A favorable score should be interpreted in light of the experimental results. It does not necessarily imply that the homology model or docked complex represents the physiological state. Instead, it may simply reflect a well-optimized mathematical solution.

Scoring functions for knowledge-based methods provide a measure of the structural environment of the model. Knowledge-based scoring functions are based on mathematical functions that consider inter-residue distances, such as side chain packing, solvation potential or solvent accessibility, and the fit of the sequence into a given protein solvent accessible surface (Zvelebil and Baum 2008). In contrast, scoring functions for potential energy methods are based on steric fit (or hindrance) of the molecular interactions derived from the van der Waals interactions between adjacent atoms, the energetics of the torsional angles for the covalent interactions, and electrostatic potential energy of the interaction (Baron et al. 2012; Náray-Szabó et al. 2012).

Modeling Time-Dependent Protein Dynamics

Molecular Dynamics Simulation Techniques

The function of most proteins is intrinsically linked to dynamic structural changes. Classical molecular dynamics (MD) simulation techniques have been used to model conformational changes of proteins and peptides on ns to μ s timescales. While many biologically important conformational changes, such as protein folding, occur over longer (μ s to ms) timescales, MD simulations are able to capture rapidly induced conformational changes, such as those involved in the process of ligand binding (10–500 ns). Recent advances in algorithm and hardware design, together with the implementation of so-called coarse-grained forcefields have extended the possible simulation times to simulate the conformational dynamics of processes such as channel gating (500 ns to 5 μ s). MD simulations are the most computationally intensive of the techniques discussed here. However, they are currently the only method (computational or experimental) that characterizes the structural dynamics and molecular interactions in atomic detail, while fully accounting for the flexibility of the protein and ligand in a physiologically relevant environment. MD simulations provide an accurate method of studying the molecular interactions involved in ligand binding; the conformational changes induced in the protein or the ligand during the formation of a stable complex; and the correlation of ligand orientation and protein conformations (Shirts 2012).

In general terms, molecular dynamics (MD) is a computer simulation of the dynamics of a set of particles under the influence of a physical force that can be described by classical physics (Alder and Wainwright 1959; Rahman 1964). Historically, MD simulations have been widely applied to problems involving a potential energy field, such as the gravitational potentials of astrophysics and cosmology (von Hoerner 1960, 1963; Rahman 1964). In the 1970s MD simulations were first coupled to molecular mechanics (MM) forcefields to investigate protein dynamics.

In MD simulations of biomolecular systems, Newtonian mechanics is used to generate a series

of time-dependent conformations of the protein system from a starting conformation (usually an experimentally determined structure) and a set of initial velocities. The potential energy of the system is described as a function of the atoms' position using a molecular mechanics (MM) forcefield. The change in energy and the forces acting on each atom are calculated at each step in the simulation. The time-dependent structural, dynamic and thermodynamic properties of the system can be calculated from the MD trajectories. As discussed earlier, one major limitation of classical MD is the limited sampling of the conformational space of the protein (or protein–ligand) system due to time-dependent trapping in local potential energy minima. Since the 1990s a number of enhanced sampling methods have been developed to address these limitations (Lorenz and Doltsinis 2012; Náray-Szabó et al. 2012; Nowak 2012).

Free Energy Calculations

One powerful application of MD simulation techniques is the estimation of the change in free energy on the binding of a drug to its target protein. This can, in principle, be directly related to the experimentally determined binding affinity. A series of methods have been developed to effectively sample the intermediate states in the transition between the ligand free in solution and the formation of the protein–ligand complex. The two most commonly used methods are free energy perturbation (FEP) and thermodynamic integration (TI). In FEP, the difference in energy between the dissociated ligand in solution and the ligand-bound complex is used to derive a thermodynamic cycle from which the binding free energy of the ligand can be calculated. In TI, the free energy difference is determined by defining a thermodynamic path between the bound and free state of the ligand. The path chosen is a simplified (mostly one-dimensional) version of the true diffusive path of the ligand binding to the protein.

The two methods have different applications. FEP methods are generally applied to small ligands or drugs with buried binding sites. Highly charged ligands can be problematic in FEP calculations due to their large solvation free energies.

TI methods are more applicable for drugs or ligands that have a surface-accessible binding mode or binding site (Gumbart et al. 2012; Jensen 2007; Shirts 2012). Independent of the method used, the task of accurately predicting the absolute binding free energies remains “a daunting computational endeavor” (Gumbart et al. 2012) and is among the most challenging types of biomolecular simulations (Shirts 2012).

Current Successes and Future Directions

The field of rational or computer-aided drug design is built on the premise that knowing the molecular structure and dynamics of a ligand binding site will enable the design of an optimized ligand molecule that can act as a more effective drug. Structural knowledge of the protein of interest and its dynamics are an essential pre-requisite for this process. Currently, the structure and dynamics of the human protein is unknown for the majority of drug targets. As experimental and modeling techniques improve, highly specific clinical drugs with minimal cross-reactivity (and side effects) are becoming a reality. The carbonic anhydrase inhibitor and anti-glaucoma drug dorzolamide was the first drug approved for clinical use that was developed by computer-aided drug design. Dorzolamide was approved for clinical use in 1995. It was rapidly followed by HIV protease inhibitors (De Lucca et al. 1997; Greer et al. 1994) and the cancer chemotherapeutic agent and tyrosine kinase inhibitor, imatinib (gleevec) (Druker and Lydon 2000). Current drugs developed by computer-aided drug design target 5-HT₃ and acetylcholine receptor agonists, G-protein coupled receptors such as CCR5 and NK1, proton pumps and TRP channels.

Summary

As computational power and modeling algorithms continue to improve, computational modeling is becoming an increasingly important investigative tool. As our experimental knowledge of protein structure increases, so too does the application of

computational modeling in elucidating the molecular details of drug binding and the mechanism by which drugs modulate protein structure and function.

Definition

Population density models are reduced descriptions of neuronal ensembles, which consist in characterizing them by the instantaneous distribution of some neuronal variables over the population. The simplest and most useful form only uses the neuron membrane potentials. The distribution of membrane potentials and its dynamical evolution can be exactly computed in different cases, for noninteracting neurons submitted to time-varying stochastic inputs. This provides the basis for the most interesting application of population density models, namely, the quantitative description of the dynamics of networks of coupled spiking neurons. The approach has in particular been used to analyze neural rhythms.

Detailed Description

Cognitive phenomena depend on the concerted activity of large populations of neurons. Understanding the dynamics of such systems has been

one of the major goals of theoretical neuroscience. Various methods have been developed to tackle this problem. These methods range from numerical simulations of large networks of spiking neurons to phenomenological “firing rate”, or “neural mass” models, in which whole populations of neurons are described by a single (or a small number of) ordinary differential equation(s), which describes the temporal evolution of the average firing rate of the population.

An intermediate and very fruitful approach consists in using a population density approach: the stochastic differential equations describing the neurons are converted in a master equation describing the probability density of the variables describing such neurons. This approach has several advantages compared to numerical simulations: in some simple models, the master equation can be solved explicitly, which gives closed form expressions for the probability density and the associated firing rate (see Fig. 1 for an illustration of the approach). In cases where exact solutions do not exist, the master equation (typically a partial differential equation, such as a Fokker-Planck equation) can be solved

Population Density Model, Fig. 1 Population density approach versus numerical simulations for a population of uncoupled leaky integrate-and-fire neurons. (a) Membrane potential of five neurons, from a simulation of a population of 10,000 neurons with stationary input ($\mu = 12.5$ mV, $\sigma = 5$ mV). Spikes are added by hand to better visualize spike

timings. (b) Probability distribution of the membrane potential (black, computed from the simulation; red, computed from the FP equation, Eq. 9). (c) Instantaneous average firing rate of the population (black, computed from the simulation in 1 ms time bins; red, computed from the FP equation, Eq. 10)

numerically, and precise estimates of the quantities of interest can be obtained much faster than using numerical simulations. Finally, this approach can be used to derive a “firing-rate” model from a population of spiking neurons, therefore building a bridge between these two modeling approaches.

In the neuronal context, population density methods (PDMs) were pioneered by Bruce Knight at the beginning of the 1970s (Knight 1972), following earlier work on simplified stochastic single neuron models (Gerstein and Mandelbrot 1964; Stein 1965). This approach was then extensively used in the 1990s (Abbott and van Vreeswijk 1993; Treves 1993; Brunel and Hakim 1999) to investigate properties of networks of spiking neurons, such as synchronization and oscillations. Initially limited to networks of integrate-and-fire neurons, it has been extended to several variants that incorporate more biophysical features of real neurons (Casti et al. 2002; Fourcaud-Trocmé et al. 2003; Brunel and Latham 2003; Richardson 2007). In this entry, we will first describe the PDM for ensembles of independent, non-connected neurons, before moving to networks. Throughout the whole entry, we focus on analytical methods; for numerical methods of integration of population density equations, see, e.g., Omurtag et al. (2000), Nykamp and Tranchina (2000), Haskell et al. (2001), and Caceres et al. (2011).

Ensemble of Independent Neurons

The most widely used model at the network level is the leaky integrate-and-fire (LIF) neuron (Lapicque 1907; Brunel and van Rossum 2007). Its simplicity makes it particularly suitable for population density approaches. We will review in this section studies of LIF neurons with different types of noise sources, before moving to several generalizations.

LIF Neurons with Independent White Noise Sources

The LIF neuron is characterized by a membrane potential $V(t)$, the subthreshold dynamics ($V < V_T$)

of which obeys the simple first-order differential equation

$$C \frac{dV}{dt} = -g_L(V - V_L) + I_{syn}(t), \quad (1)$$

where C is the capacitance, g_L the leak conductance, V_L the leak (resting) potential, and $I_{syn}(t)$ the synaptic input currents.

This equation is often rewritten as

$$\tau_m \frac{dV}{dt} = -V + \tilde{I}_{syn}(t), \quad (2)$$

where $\tau_m = C/g_L$ is the membrane time constant and $\tilde{I}_{syn}(t)$ are synaptic inputs in membrane potential units.

In the LIF model, spikes are emitted whenever $V = V_T$; the voltage is then reset to $V = V_r$ after an absolute refractory period of duration τ_{rp} . This simple spike-and-reset mechanism replaces Na and K currents in more realistic models using the Hodgkin-Huxley formalism.

The LIF model can be further simplified by removing the leak term or making leak voltage independent and implementing a lower bound on voltage. In the first case, this leads to the “perfect” (PIF) or “simplified” (SIF) integrate-and-fire neuron (Knight 1972; Fourcaud and Brunel 2002) and, in the second case, to the “constant leakage integrate-and-fire neuron with floor” (CLIFF) (Fusi and Mattia 1999; Rauch et al. 2003).

In vivo, neurons in the central nervous systems receive highly irregular inputs, leading to large fluctuations of their membrane potentials. This motivates the study of stochastic models for the synaptic currents. A model of interest is a LIF neuron with Poisson inputs

$$\tau V = -V + I(t),$$

where $I(t)$ is a Poisson process with (possibly time-dependent) rate v_{in}

$$I(t) = J\tau \sum_k \delta(t - t_k), \quad (3)$$

where J is the amplitude of postsynaptic potentials (PSPs) elicited by single spikes and t_k are the times of presynaptic spikes.

A second model of interest is derived from the first through a diffusion approximation. When J is small, and τv is large, $I(t)$ can be approximated by

$$I(t) = J\tau \sum_k \delta(t - t_k) \approx \mu(t) + \sigma(t)\sqrt{\tau}\eta(t), \quad (4)$$

where $\mu = Jv_m\tau$, $\sigma^2 = J^2v_m\tau$, and $\eta(t)$ is a white noise ($\langle\eta(t)\rangle = 0$, $\langle\eta(t)\eta(t')\rangle = \delta(t - t')$).

With such a stochastic input, the voltage becomes an Ornstein-Uhlenbeck (OU) process, which obeys a Langevin equation

$$\tau \frac{dV}{dt} = -V + \mu + \sigma\sqrt{\rho}\eta(t). \quad (5)$$

A discretized version of Eq. 5 becomes in the limit $dt/\tau \rightarrow 0$

$$V(t + dt) = V(t)(1 - dt/\tau) + \mu dt/\tau + \sqrt{(dt/\tau)}\sigma Z(t).$$

A population of neurons with independent noise terms can be described by the probability density of the voltage $P(V, t)$, which is described by Fokker-Planck equation (see, e.g., Risken 1984; Gardiner 1986, and entry on ► “Fokker-Planck Equation”):

$$\tau_m \frac{\partial P(V, t)}{\partial t} = \frac{\sigma^2(t)}{2} \frac{\partial^2 P(V, t)}{\partial V^2} + \frac{\partial}{\partial V} \times [(V - \mu(t))P(V, t)], \quad (6)$$

which can be rewritten as a continuity equation,

$$\frac{\partial P}{\partial t} + \frac{\partial j}{\partial V} = 0,$$

where j is the probability flux. The boundary conditions link the density P with the instantaneous firing probability v :

- At threshold V_t , the probability flux at V_t defines the instantaneous firing probability $v(t)$, leading to the boundary 1

$$P(V_t, t) = 0, \quad \frac{\partial P}{\partial V}(V_t, t) = -\frac{2v(t)\tau_m}{\sigma^2(t)}. \quad (7)$$

- At reset potential V_r , what comes out at V_t must come back at V_r :

$$\begin{aligned} P(V_r^-, t) &= P(V_r^+, t), \quad \frac{\partial P}{\partial V}(V_r^-, t) - \frac{\partial P}{\partial V}(V_r^+, t) \\ &= -\frac{2v(t)\tau_m}{\sigma^2(t)}. \end{aligned} \quad (8)$$

Note that in the above equations, the refractory period τ_{rp} has been set to zero. These equations can be easily generalized to nonzero τ_{rp} (Brunel 2000b).

This Fokker-Planck equation can be solved numerically for arbitrary time-dependent inputs or solved analytically in the following two cases:

Time-Independent Input Statistics

For constant $\mu = \mu_0$ and $\sigma = \sigma_0$, Eqs. 6, 7, and 8 yield

$$\begin{aligned} P_0(V) &= \frac{2v_0\tau_m}{\sigma} \exp\left(-\frac{(V - \mu_0)^2}{\sigma^2}\right) \\ &\quad \int_{\frac{V - \mu_0}{\sigma}}^{\frac{V_r - \mu_0}{\sigma}} \exp(u^2)\Theta(u - V_r)du \\ v_0 &= \frac{1}{\tau_m\sqrt{\pi} \int_{\frac{V_r - \mu_0}{\sigma}}^{\frac{V_r - \mu_0}{\sigma}} \exp(u^2)[1 + \text{erf}(u)]}, \end{aligned} \quad (9)$$

which were, to our knowledge, first derived by Siegert for general OU processes (Siegert 1951) and then applied to the neuronal context by Ricciardi (Ricciardi 1977). In the case of a non-zero refractory period τ_{rp} , the “Siegert-Ricciardi” formula becomes

$$v_0 = \frac{1}{\tau_{rp} + \tau_m\sqrt{\pi} \int_{\frac{V_r - \mu_0}{\sigma}}^{\frac{V_r - \mu_0}{\sigma}} \exp(u^2)[1 + \text{erf}(u)]}. \quad (10)$$

The “static transfer function” $v_0 = \Phi(\mu, \sigma)$ is shown as a function of μ for various values of σ in Fig. 2a and as a function of σ for various values of μ in Fig. 2b.

Time-Varying Input Statistics: Linear Response and Spike-Rate Response Function

Solving Eqs. 6, 7, and 8 analytically is much harder when μ and σ are time dependent. A possible solution is to apply a perturbative approach. The idea is to consider a small amplitude temporal modulation of the inputs, $\mu(t) = \mu_0 + \varepsilon\mu_1(t)$, where ε is a small parameter. One can then write

$$P(V, t) = P_0(V) + \varepsilon P_1(V, t) + O(\varepsilon^2) \quad (11)$$

$$v(t) = v_0 + \varepsilon v_1(t) + O(\varepsilon^2), \quad (12)$$

insert Eqs. 11 and 12 in Eq. 6, and expand the resulting equation in ε . The zeroth-order term in ε in that equation yields the stationary solution, Eqs. 9 and 10. The first-order term can be solved by Fourier transform, by writing the input modulation as a superposition of harmonic oscillations

$$\mu_1(t) = \sum_{\omega} [\tilde{\mu}_1(\omega) \exp(i\omega t) + \tilde{\mu}_1^*(\omega) \exp(-i\omega t)], \quad (13)$$

where we have denoted complex conjugation by the star symbol. This leads to an inhomogeneous 2nd-order ODE for $\tilde{P}_1(V, \omega)$, whose boundary conditions involve $v_1(\omega)$. $\tilde{v}_1(\omega)$ describes the amplitude and phase shift of the instantaneous firing rate, when the input oscillates in time with frequency ω . The calculation shows that $v_1(\omega)$ is proportional to the input modulation $\tilde{\mu}_1^*(\omega)$,

$$v_1(\omega) = \tilde{R}_{LIF}(\omega) \tilde{\mu}_1(\omega). \quad (14)$$

The coefficient of proportionality $\tilde{R}_{LIF}(\omega)$ is the linear firing-rate response. It determines how an input modulation at a frequency ω is amplified (or attenuated) by the LIF neuron. The linear firing-rate response $\tilde{R}_{LIF}(\omega)$ is displayed in Fig. 2c–e. The amplitude of $\tilde{R}_{LIF}(\omega)$ shows strong resonances at frequencies that are integer

multiples of the baseline firing rate, for small noise and large firing rates. Otherwise, the response is the one of a low-pass filter, with an attenuation at high frequencies that decay as $1/\sqrt{\omega}$.

A second strategy is to use an expansion in eigenfunctions of the Fokker-Planck operator (Risken 1984; Knight et al. 2000; Mattia and Del Giudice 2002; Mattia and Del Giudice 2004; Ostojic and Brunel 2011). This approach has the advantage that it is not limited to time-dependent inputs with small amplitude.

LIF Neurons with More Realistic Noise Models

As already discussed, a large part of the fluctuations in neurons of the CNS in vivo originate from the bombardment of spikes from presynaptic neurons, which generate fluctuating synaptic conductances. As discussed above, the resulting total synaptic current is often modeled as additive white noise. However, synaptic currents differ substantially from white noise in at least three respects: (i) they are the sum of a discrete number of individual events and hence can be better described by a filtered point process; (ii) the currents are voltage-dependent, and therefore, noise has a multiplicative component; and (iii) individual synaptic currents have a finite decay time, which leads to finite correlation time constants. Several groups have consequently investigated how to incorporate these more realistic features in the PDM.

Shot Noise

Spike trains have long been modeled as point processes, and it has been argued that the statistics of firing of neurons in many parts of the brain (in particular, in the cortex) bear similarities to a simple Poisson process (in particular, the CV of cortical neurons in vivo is typically close to 1) (Softky 1993; Shadlen and Newsome 1994). Consequently, several authors considered synaptic inputs as Poisson processes (Stein 1965; Richardson and Gerstner 2005; Richardson and

Population Density Model, Fig. 2 LIF transfer functions. (a) Static transfer function, Eq. 10: Firing rate as a function of μ for $\sigma = 1$ mV (black), 3 mV (red), 10 mV (green). (b) Static transfer function, Eq. 10: Firing rate as a function of σ , for $\mu = 15$ mV (black), 20 mV (red), 25 mV (green). (c) Amplitude of firing-rate modulation, as a function of frequency of input modulation, for $\sigma = 1$ mV and $v_0 = 1$ (black), 3 (gray), 10 (brown), 30 (red), 100 (orange). Note the strong resonances at integer multiples of the firing rate, which are present for large-enough firing rates, and the $1/\sqrt{f}$ decay at high frequency.

(d) Amplitude of firing-rate modulation, as a function of frequency of input modulation, for $\sigma = 10$ mV, and same values of the firing rates as in C. Note that the resonances are no longer present, due to strong noise, but the high-frequency behavior is qualitatively unchanged. (e) Phase shift of firing-rate modulation, as a function of frequency of input modulation (same parameters as in c). (f) Phase shift of firing-rate modulation, as a function of frequency of input modulation (same parameters as in d)

P

Swarbrick 2010; Helias et al. 2011). The membrane potential fluctuations are therefore described by a shot noise, with instantaneous jumps in the membrane potential occurring at random times. The master equation describing the temporal evolution of the distribution of membrane potential becomes a partial differential-difference equation, which can be solved analytically when the distribution of EPSP amplitudes is exponentially distributed (Richardson and Swarbrick 2010). Using these calculations, it was shown that the diffusion approximation is very good for small PSP amplitudes (<1 mV), but that significant deviations appear for larger PSP amplitudes.

Multiplicative Noise

Another feature of synaptic currents is their voltage dependence. Synaptic currents are induced by ion flow through receptor channels upon binding of neurotransmitter and are therefore dependent on the membrane potential of the cell. This dependence can be described by a linear “driving force” which vanishes at the associated reversal potential, which is close to 0 mV for excitatory glutamatergic synapses and -80 mV for inhibitory GABAergic synapses. This leads to a multiplicative noise, i.e., to a voltage-dependent σ in Eq. 6. The resulting equation can still be solved in the stationary case, and analytical results can also

be obtained for the linear firing-rate response (Richardson 2004, 2007; Richardson and Gerstner 2005).

Temporally Correlated Noise

Synaptic currents $I(t)$ have finite temporal width, and this is often modeled using a first-order equation

$$\tau_s \frac{dI(t)}{dt} = -I + J\tau_m \sum_k \delta(t - t_k),$$

where τ_s is the synaptic time constant. Instead of being delta functions, PSCs are now described by instantaneous jumps followed by an exponential decay with a time constant τ_s .

In the diffusion limit, this leads to a system of two differential equations:

$$\tau_m \frac{dV}{dt} = -V + I_{syn}(t). \quad (15)$$

$$\tau_s \frac{dI_{syn}}{dt} = -I_{syn}(t) + \mu + \sigma\sqrt{\tau_m}. \quad (16)$$

The system is therefore described by a 2D FP equation, which can only be solved in asymptotic limits, as in the limits of short ($\tau_s \ll \tau_m$) and long ($\tau_s \gg \tau_m$) synaptic time constant (Brunel and Sergi 1998; Brunel et al. 2001; Fourcaud and Brunel 2002; Moreno and Parga 2004).

More Realistic Neurons

The LIF model has been criticized because it lacks many of the features of real neurons: (i) spike generation dynamics, (ii) voltage-gated currents active in the subthreshold range (iii) currents leading to firing-rate adaptation, and (iv) finally, spatial structure. To incorporate such features, a common strategy is to use the Hodgkin-Huxley formalism to describe the dynamics of voltage-gated channels (to account for features i–iii) and/or compartmental models to describe the spatial structure of the model (to account for

iv). However, the resulting models are quite complex and therefore not suited for analytical studies or population density approaches.

Another strategy is to devise simplified models in the spirit of the LIF model, which strive to keep simplicity, yet exhibit more realistic features than the LIF. We now address briefly models that tackle issues (i–iii) discussed above.

Nonlinear IF Neurons

A simple extension of the LIF that describes in a simple fashion the dynamics of spike generation is to add a suitable nonlinearity to the voltage dynamics. Such models can be described by the equation

$$\tau_m \frac{dV}{dt} = -V + \psi(V) + I_{syn}(t), \quad (17)$$

where $\psi(V)$ is a nonlinear function of voltage (Fourcaud-Trocmé et al. 2003). With a suitable choice of $\psi(V)$ (in particular, it has to be supra-linear at large V), the membrane potential diverges to infinity in finite time if the synaptic inputs exceed some threshold. The time of divergence to infinity defines spike timing (it is also possible to define for practical purposes a large but finite voltage threshold). Then, as in the LIF model, the voltage is reset to some potential V_r after a refractory period τ_{rp} .

This model introduces two modifications to the standard FP equation for the LIF: (i) one has to introduce the function $\psi(V)$ in the drift term, which becomes $\partial_v[(V - \psi(V))P(V, t)]$; the boundary condition for the threshold becomes a boundary condition at $V = \infty$:

$$v(V) = \frac{1}{\tau_m} \lim_{V \rightarrow \infty} \psi(V)P(V, t).$$

Several choices for the function $\psi(V)$ have been proposed: in particular, quadratic (Ermentrout and Kopell 1986; Ermentrout 1996; Gutkin and Ermentrout 1998; Latham et al. 2000), quartic (Touboul 2008), or exponential functions (Fourcaud-Trocmé et al. 2003). Fourcaud-Trocmé

et al. (2003) found that an exponential nonlinearity is the choice that best approximates the dynamics of neuron models with fast sodium current described by the Hodgkin-Huxley formalism – in particular the WB (Wang and Buzsáki 1996) model. Badel et al. showed that the exponential nonlinearity fits very well-effective I-V curves of both pyramidal cells and fast-spiking interneurons in the cortex (Badel et al. 2008a, b). For both reasons, the EIF neuron is nowadays thought to be the best choice among the family of nonlinear integrate-and-fire neurons.

A Fokker-Planck formalism has been used to derive the static transfer functions of both QIF and EIF neurons (Brunel and Latham 2003; Fourcaud-Trocmé et al. 2003) and the high-frequency behavior of their dynamical transfer function (Fourcaud-Trocmé et al. 2003; Richardson 2007). A simple and efficient numerical method has been developed to obtain these quantities from the Fokker-Planck equation (Richardson 2007). A notable difference with LIF neurons is that spike response function decays at high frequency as $1/f$ (resp. $1/f^2$) for EIF (resp. QIF) neurons, while it decays as $1/\sqrt{f}$ for LIF neurons (see Fig. 2).

Two-Variable Models

An extension of the basic LIF model that leads to richer subthreshold dynamics consists in adding a second variable coupled to the voltage:

$$\tau_m \frac{dV}{dt} = -V + \gamma W + I_{syn}(t). \quad (18)$$

$$\tau' \frac{dW}{dt} = -W + V. \quad (19)$$

These equations can be derived from models using the Hodgkin-Huxley formalism through a linearization around a stable subthreshold potential (see, e.g., Richardson et al. (2003)). The W variable is related to the activation (or inactivation) variable of a current that contributes to the dynamics in the subthreshold range (typical examples are the mixed cationic

H current or various types of potassium currents). This additional variable can lead to subthreshold resonance, provided γ is negative and large enough. The model described by Eqs. 18 and 19 and equipped with a firing threshold and reset has been termed generalized integrate-and-fire (GIF) by Richardson et al. (2003). The resonate-and-fire model of Izhikevich (2001) is a special case of the GIF model. Population density methods have been applied to determine both static and dynamical response properties of this model (Richardson et al. 2003; Brunel et al. 2003).

Another extension of the basic LIF model is to add again a second variable, but which unlike Eqs. 18 and 19 does not depend on the voltage but rather purely on spikes:

$$\tau_m \frac{dV}{dt} = -V + \gamma W + I_{syn}(t). \quad (20)$$

$$\tau' \frac{dW}{dt} = -W. \quad (21)$$

When a spike is emitted by the neuron, the W variable makes a jump, $W \rightarrow W + 1$. This model can describe the phenomenon of “firing-rate adaptation” whereby the firing rate of a neuron steadily decreases upon injection of a constant current. This model is sometimes called “adaptive LIF” model, or LIF model with adaptation.

The two-dimensional models described so far have linear subthreshold dynamics. Other models have introduced nonlinearities in the subthreshold dynamics. In order to reproduce the basic features of the bursting behavior of thalamocortical relay neurons, Smith et al. (2000) introduced an integrate-and-fire-or-burst model by adding an additional slow variable to the basic integrate-and-fire model:

$$\begin{aligned} c \frac{dV}{dt} &= -g_L(V - E_L) - g_T \Theta(V - V_h) h(V - E_T) + I_{syn}(t) \\ \frac{dh}{dt} &= \begin{cases} -h/\tau_h^- & (V > V_h) \\ (1-h)/\tau_h^+ & (V < V_h) \end{cases}, \end{aligned} \quad (22)$$

where the Heaviside function $\Theta(V - V_h)$ represents an instantaneous idealization of the fast activation of the low-threshold calcium

current I_T , while the slow variable h represents the inactivation of the low-threshold calcium. The dynamics of h is governed by Eq. 22: it relaxes to zero with time constant τ_h^- – when the voltage is above V_h , while it relaxes to unity with a slower time constant τ_h^+ when the voltage is below V_h . This model captures the qualitative features of bursting dynamics of thalamic relay cells. In particular, when a current step is applied to the model, the response depends drastically on the initial membrane potential: (i) If V is initially below V_h , the model generates a single burst of spikes. This is due to the fact that initially $h = 1$; when the voltage is depolarized to a value large than V_h , the I_T current provides a strong depolarization that generates the burst. The burst is terminated because of the decay of the variable h to zero with time constant τ_h^- . (ii) If V is initially above V_h , then $h = 0$ – hence, the I_T current remains inactivated and the dynamics is identical to an LIF neuron. The dynamics of a population of such neurons were subsequently studied by Casti et al. (2002).

Izhikevich (2003) and Brette and Gerstner (2005) have proposed two-variable models that include a nonlinearity in the voltage equation (quadratic in Izhikevich and exponential in Brette and Gerstner). These models are able to reproduce a wide variety of electrophysiological behaviors, depending on parameters (Touboul 2008; Naud et al. 2008). Another model was introduced by Badel et al. (2008b) to fit quantitatively electrophysiological data: an EIF model with a dynamical threshold V_T , which increases after each spike and relaxes exponentially in between spikes. Finally, Richardson (2009) proposed a generalized exponential model (GEM): a two-variable model in which the voltage obeys EIF dynamics, with a second variable which depends on the voltage in a nonlinear fashion. He then generalized the method developed in Richardson (2007) to compute static and dynamical response functions, in the limit in which the second variable evolves on a much slower time scale than the voltage.

From Ensemble of Spiking Neurons to Rate Models

Population density methods provide a way to capture accurately the dynamics of the mean instantaneous firing rate of a population of neurons. A long-standing question in theoretical neuroscience is whether this dynamics can be approximated by a system of a small number of ordinary differential equations (ODEs; in other words, a rate or neural mass model) (Ermentrout 1994; Shriki et al. 2003). Two main possible approximation schemes have been devised. In the case when there is a slow synaptic time constant, the instantaneous firing rate can be computed for a given value of the synaptic current, and the dynamics of the system is then given by a simple ODE describing the temporal evolution of the slow synaptic variable (Ermentrout 1994). In the case when the network is composed of EIF neurons, a rate model approximation can be derived analytically based on the specific properties of the linear firing-rate response of this model (in particular, the decay in $1/f$ at high frequency), which is shown to describe accurately the dynamics of the instantaneous firing rate of the network (Ostojic and Brunel 2011).

Ensembles of Connected Neurons

One of the most interesting aspects of the population density approach is that it offers a way to analyze quantitatively the dynamics of ensembles of connected neurons. It allows one to relate the firing properties of a network (rate of spike emission, presence of global oscillations, frequency of these oscillations) to the biophysical characteristics of single neurons (ionic channel content, membrane impedance, mechanism of action potential generation, neuronal geometry) and of their synaptic connections (rise and decay time of synaptic currents, reversal potential, presence and characteristics of electrical connections). The main and classical idea is not to take into account the precise realization of the

network connectivity but rather to replace the specific presynaptic neurons that influence a given neuron by random members of the same class. This neglect of pair correlations constitutes the central tenet of “mean-field” theories in statistical mechanics that date back at least to Boltzmann’s derivation of his kinetic equation (Lifshitz and Pitaevskii 1981) and to Curie and Weiss theory of ferromagnetism (Lifshitz and Pitaevskii 1980). In the simplest case of a homogeneous network, all neurons are considered to belong to the same class. In more complicated cases, one can group in different classes neurons of different types, e.g., excitatory or inhibitory, or neurons which differ in electrophysiological properties (ionic channel content) or inputs (synaptic strengths or numbers). This approximation allows one to use the population density approach for independent neurons, as described in the previous section, Ensembles of Independent Neurons, in a “self-consistent” way. Namely, the characteristics of the inputs of one neuron of a given class, which influence its dynamical behavior, depend themselves on the dynamics of the neurons in the different classes. Therefore, the dynamics of the different classes of neurons should all be determined at once. Before describing this procedure in a more detailed way, we briefly recall the basic elements in the mathematical description of a neuronal network.

Mathematical Description of a Neuronal Network

The dynamics of a neuronal network depends on the characteristics of the different neurons in the network as well as on the specific connectivity of the network. Even when one considers electrophysiologically compact neurons and restricts oneself to the single-compartment models described in the previous sections (LIF, nonlinear IF, two-variable models), the network dynamics is described by an ensemble of equations of the following type:

$$\begin{aligned}\tau \frac{dV_i}{dt} &= F_i(V_i, W_i^\alpha) + I_i^{(s)}(t) \rightarrow \\ \frac{dW_i^\alpha}{dt} &= G_i^\alpha(V_i, W_i^\alpha).\end{aligned}\quad (23)$$

In Eq. 23, V_i is the membrane potential of neuron i and W_i^α is the set of supplementary (gate) variables in the considered model when there are some. In contrast to the case of uncoupled neurons, the synaptic current $I_i^{(s)}(t)$ comes in part from the inputs that neuron i receives from other neurons in the network. This couples the dynamics of different neurons in the network and renders the set of Eq. 23 difficult to analyze. Population density approaches provide a very useful way to tackle this problem.

The coupling between neurons at synapses influences the network dynamics and it needs to be precisely described. Let us denote by $J_{ij}s(t - t_k)$ the unitary synaptic current received by neuron i when its presynaptic neuron j emits a spike at time t_k ($J_{ij} > 0$ if neuron j is excitatory, while $J_{ij} < 0$ if neuron j is inhibitory). Then, the full synaptic current $I_i^{(s)}(t)$ in neuron i is obtained as the sum of synaptic currents created by all presynaptic spikes, i.e., spikes emitted at times t_j^k in the presynaptic neuron j :

$$I_i^{(s)}(t) = \sum_j J_{ij} \sum_k S(t - t_j^k). \quad (24)$$

Similar to neurons, synaptic currents can be described with various levels of complexity, as already discussed in the previous section. The simplest models use the so-called “current-based” description of synaptic inputs, in which the current is independent of the voltage. A more accurate description, discussed in the section “Multiplicative Noise”, takes a voltage-dependent $J \propto g(V - V_{rev})$ where g is the synaptic conductance and V_{rev} is the corresponding reversal potential – the “conductance-based” description.

In the crudest approximation, similar to that of Eq. 3, the time course of the synaptic current is forgotten. One simply takes

$$S(t) = \tau \delta(t - D), \quad (25)$$

where the time D accounts in an approximate way for the delay between spike emission in the pre-synaptic neuron and depolarization of the post-synaptic neuron. However, synaptic currents have finite temporal width, as pointed out in the section “Temporally Correlated Noise”. Thus, in a more accurate description, the time course of the post-synaptic current elicited by a single spike can be modeled by a delayed difference of exponentials. When a spike is emitted at time $t = 0$, the current is zero until $t = D$, where D is the delay, or latency, of the synaptic connection. Then, the current is described by

$$S(t) = \frac{\tau}{\tau_r - \tau_d} \left[\exp\left(-\frac{(t-D)}{\tau_d}\right) - \exp\left(-\frac{(t-D)}{\tau_r}\right) \right] H(t-D), \quad (26)$$

where $\tau_r < \tau_d$ describe the rise and decay times of the current, respectively, and H is the Heaviside function ($H(x) = 1$ for $x > 0$ and $H(x) = 0$, otherwise). This can be equivalently described by the system of differential equations

$$\begin{aligned} \tau_d \frac{dS}{dt} &= -S + X \\ \tau_r \frac{dX}{dt} &= -X + \tau \delta(t - D). \end{aligned}$$

Typical values for the time constants are $D \sim 1$ ms; τ_r and τ_d vary widely depending on receptor type, but are $\tau_r < 1$ ms and $\tau_d \sim 2$ –10 ms for the fast (AMPA and GABA_A) receptor-mediated synaptic responses (note that the synaptic current rise was taken to be instantaneous in section “Temporally Correlated Noise”).

For simplicity, we will mostly consider in this brief review networks with a fixed connectivity and time-independent synaptic strengths J_{ij} . It should however be noted that synapses in the CNS undergo plasticity at various time scales. In particular, short-term depression and facilitation (on time scales of 100 s of ms) potentially play an important role in several dynamical phenomena. Very few

investigations using population density methods have however included plastic synapses (Romani et al. 2006).

Standard Coupling Regime and Mean-Field Approximation: The Simplest Case of a Homogeneous Neuronal Population

The case of a network consisting of a single homogeneous population of LIF model neurons provides a simple example of the self-consistent population density approach.

Thus, we consider a network of N identical LIF neurons, with each neuron receiving inputs from a large number C of randomly chosen other neurons in the network ($C \sim 10,000$ is a typical number for neurons in the CNS). We suppose that the neurons receive as well inputs from neurons outside the network and we describe these, as in Eq. 4, by their mean μ_{ext} and their fluctuations $\sigma_{ext} \sqrt{\tau} \eta_i(t)$, $i = 1, \dots, N$, where $\eta_i(t)$ is a white noise that we suppose uncorrelated on different neurons ($\langle \eta_i(t) \eta_j(t') \rangle = \delta_{ij} \delta(t - t')$). In this model, the membrane potential of neuron i obeys

$$\tau \frac{dV_i}{dt} = -V_i + I_i^{(s)}(t) + \mu_{ext} + \sigma_{ext} \sqrt{\tau} \eta_i(t). \quad (27)$$

In Eq. 27, $I_i^{(s)}(t)$ describes the total synaptic current received by neuron i . It is the sum over all presynaptic neurons j and over all their emitted spikes at times t_j^k of the unitary synaptic currents $J_{ij} S(t - t_j^k)$:

$$I_i^{(s)}(t) = \sum_j J_{ij} \sum_k S(t - t_j^k). \quad (28)$$

For $I_i^{(s)}(t)$ to remain of reasonable amplitude when C is large, each synapse of neuron i should be of strength $\sim 1/C$. When pair correlations between spike emissions are negligible, or neglected in a mean-field approximation, the sum of this large number of weak synaptic currents gives a total synaptic current which depends on the mean rate $v(t)$ of spike emission by the

presynaptic neurons and has negligible fluctuations¹:

$$I_i^{(s)}(t) = CJ \int^t S(t-t')v(t')dt'. \quad (29)$$

The synaptic current (29) only depends on the total number C of synaptic connections received by neuron i and not on the precise network connectivity. In the considered random homogeneous network, each neuron statistically behaves in the same way. This stochastic dynamics can be described by the previous Eq. 6:

$$\tau_m \frac{\partial P(V,t)}{\partial t} = \frac{\sigma_{ext}^2}{2} \frac{\partial^2 P(V,t)}{\partial V^2} + \frac{\partial}{\partial V} \times [(V - \mu(t))P(V,t)]. \quad (30)$$

The difference between the present Eq. 30 and the previous Eq. 6 is that in Eq. 30, the current $\mu(t)$ is not entirely prescribed by the external drive but also depends through the synaptic current on the coupling between the neurons in the network:

$$\mu(t) = \mu_{ext} + CJ \int^t s(t-t')v(t')dt'. \quad (31)$$

The current $\mu(t)$ depends on the instantaneous discharge rate of the neurons in the network, which itself depends on the solution of Eq. 30 (see Eq. 7). Therefore, Eqs. 30 and 31 should be solved simultaneously to determine the network characteristics. We provide several examples of how this is done in the following.

Steady-State Firing Rates

We begin by considering a network that is in a stationary state, namely, with the spike emission rate $v(t)$ independent of time, $v(t) = v_0$. Such a stationary state is sometimes called an *asynchronous state*. How is v_0 determined as a function of

the connection strength J , the number of synapses C , the neuron membrane time constant, or other parameters?

In a time-independent situation, the current drive $\mu(t)$ (Eq. 31) is constant in time, $\mu(t) = \mu_0$. It is simply given as a function of the neuron spike emission rate v_0 by

$$\mu_0 = \mu_{ext} + CJv_0 \quad (32)$$

When this is used in the FPE (30) to obtain the neuron discharge rate, one obtains, as for uncoupled neurons, the Siegert-Ricciardi formula (10):

$$v_0 = \frac{1}{\tau_{ip} + \tau_m \sqrt{\pi} \int_{\frac{V_r - v_{ext} - CJv_0}{\sigma_{ext}}}^{\frac{\sigma_{ext}}{V_r - v_{ext} - CJv_0}} \exp(u^2)[1 + \text{erf}(u)] du}. \quad (33)$$

In contrast to the usual Siegert-Ricciardi formula (10), v_0 appears on both sides of Eq. 33. The spike emission rate v_0 should thus be obtained as a root of the nonlinear Eq. 33. For inhibitory neurons ($J < 0$), it is easy to see, for instance, graphically, that Eq. 33 has a unique root. In contrast, for an excitatory network, no solution exists for J large enough when individual neurons have no refractory period. This reflects the fact that the neuron discharge rate diverges to infinity in this case. Introducing a finite refractory period $\tau_{rp} > 0$ leads to saturation of the rates. In this case, there exists an interval of values of μ_{ext} for which three solutions to Eq. 33 exist, provided J is large enough (Amit and Brunel 1997; Brunel 2000b).

Linear Stability Analysis and Emergence of Oscillations

Besides steady-state firing rates, the main interest of the population density approach is to analyze the dynamics of network of neurons. We illustrate the idea on the simple example of the recurrent network of inhibitory neurons considered above (see Brunel and Hakim 1999; Brunel and Wang 2003; Brunel and Hansel 2006 for more details). When the dynamics is stationary at the network

¹ The important case of excitation-inhibition balance in a multi-population network, which allows for stronger synapses and fluctuations in the noise variance, is discussed in section “Strong Coupling Regime.”

level, the neuron discharge rate is determined by Eq. 33. However, such an asynchronous state can be unstable. For some neuronal and/or synaptic parameters, the neurons can synchronize their discharges and produce a global oscillatory rhythm or more complex dynamics. A simple test consists in investigating whether a small collective fluctuation grows or decays. The analysis proceeds similarly to the previously considered case of an external time-dependent input with the difference that the time dependence of the input is generated by the network itself and has therefore to be determined self-consistently. We consider a time-dependent input current $\mu(t) = \mu_0 + \mu_1(t)$. Linearization of Eq. 30 and solution of the resulting linear equations then relate the modulation of the firing rate of the neurons of the network to the modulated input. At the linear level, it is sufficient to consider perturbations that evolve in an exponential way since the dynamical evolution of a general perturbation can be reconstructed by superposition of those. One can thus focus on input and firing-rate modulations, $\mu_1(t) = \tilde{\mu}_1(\lambda) \exp(\lambda t) + \tilde{\mu}_1^*(\lambda) \exp(\lambda^* t)$ and $v_1(t) = \tilde{v}_1(\lambda) \exp(\lambda t) + \tilde{v}_1^*(\lambda) \exp(\lambda^* t)$. Solving the linear evolution equation shows that the firing rate modulation is given by the product of the neuronal firing rate response and the input modulation,

$$v_1(\lambda) = \tilde{R}_{LIF}(\lambda) \tilde{\mu}_1(\lambda). \quad (34)$$

Up to this stage, there are no differences with the previous treatment of an external input current. Thus, how is the dynamics of μ_1 self-generated? In a recurrent network, the input-modulated current in a given neuron is actually the synaptic current that results from the spikes in its presynaptic neurons. The two are therefore related by the synaptic dynamics as described by Eq. 31. For exponentially modulated time courses, this relation simply reads

$$\tilde{\mu}_1(\lambda) = CJS(\lambda)v_1(\lambda). \quad (35)$$

Comparison between Eq. 34 provides the equation that determines the values of the growth/decay exponent λ , namely, the dynamics, in the linear regime, of a (small) perturbation

$$CJS(\lambda)R_{LIF}(\lambda) = 1 \quad (36)$$

For a synaptic current described by Eq. 26, the function $S(\lambda)$ depends on the synaptic rise and decay times, τ_r and τ_d , as well as on the delay D :

$$S(\lambda) = \frac{\tau \exp(-\lambda D)}{(1 + \lambda \tau_r)(1 + \lambda \tau_d)}. \quad (37)$$

Even without a detailed analysis, one can see how information about the dynamics can be extracted from Eq. 36. For instance, taking its modulus and assuming that $|R_{LIF}(\lambda)|$ is bounded (which is true for $\sigma > 0$), one sees that for small $|J|$, Eq. 36 can be satisfied only when the synaptic function compensates for the smallness of $|J|$. That happens only for $\text{Re}(\lambda) < 0$ when the modulus of the exponential term can become larger than 1 or when λ is close to $-1/\tau_r$ or $-1/\tau_d$ so that the denominator in Eq. 37 is small. Thus, for small-enough synaptic strengths, the network stationary state is found to be linearly stable. This can change as $|J|$ increases. At the critical synaptic strength J_c at which the real part of an eigenvalue changes from negative to positive, $\text{Re}(\lambda) = 0$ and Eq. 36 should have a purely imaginary solution $\lambda = i\omega$. This happens for an inhibitory network ($J < 0$) and signals the spontaneous appearance of oscillations in the discharge rate of the network, namely, a neural rhythm at the frequency ω . By taking the argument of Eq. 36, ω is found to obey

$$\pi = \omega D + \arctan(\omega \tau_r) + \arctan(\omega \tau_d) - \arg[R_{LIF}(\omega)], \quad (38)$$

where the π on the left-hand side come from the inhibitory character of the synaptic current. The oscillation frequency ω is mostly determined by the synaptic constant. The observed fast (200 Hz) cerebellar rhythm has been proposed by de Solages et al. (2008) to be a physiological realization of this kind of fast oscillation driven by recurrent inhibition. The population density formalism has similarly been used to analyze the dynamics of a variety of other networks. We briefly review some of the obtained results in the following section.

Networks Analyzed by the Population Density Approach

Electrically Coupled Neurons

Chemical synapses of different types play a major role in information transmission in the nervous system. We have briefly summarized above how excitatory and inhibitory transmission can be modeled. Electrical coupling mediated by gap junctions between cells is also widespread. In particular, specific electrical coupling has been found between interneurons of the same type (Galarreta and Hestrin 1999; Gibson et al. 1999). This has motivated several theoretical analyses to try and gain a better understanding of electrically connected neural assemblies. Population density models are particularly appropriate to address this issue.

At the simplest level, electrical coupling is simply taken to be an electrical conductance between the two coupled cells. The current in cell i coming with its coupling with cell j is then

$$I_i = G_e(V_j - V_i). \quad (39)$$

A spike in cell j then produced a filtered “spikelet” current injection in cell i . An effective way of accounting for this phenomenon has been proposed for LIF neurons since spike shape is not explicitly described in this simplified electrophysiological model (Lewis and Rinzel 2003). The fast part of the spikelet is taken to be a δ -function depolarization in neuron i which accompanies every spike in cell j very similar to the simplified description of chemical transmission by Eq. 25. Equation 39 is implemented as such at all other times. Reset after a spike or spike after hyperpolarization (AHP) in more realistic descriptions in neuron j can produce in the model as in reality a hyperpolarizing current in cell j , as is not always well appreciated. The population density model based on this simplified description allows one to better understand the effect of these two opposite effects of depolarization by fast spike transmission and hyperpolarization due to AHP transmission. In both cases, a transition from a stationary steady state to a synchronized oscillation is found for large-enough coupling conductances and

low-enough noise. But the transition to synchrony itself has a different character. Interestingly when hyperpolarization dominates over depolarization, the oscillatory state and the stationary state are found to coexist in a window of parameters. The network is bistable between these two different states and its history determines whether it oscillates or not (Ostojic et al. 2009).

Excitatory-Inhibitory Networks

Most networks of the central nervous system are composed of excitatory and inhibitory neurons. Population density models have proven of great help in extracting some general dynamical characteristics of networks of interacting excitatory and inhibitory neurons. Using a self-consistent approach similar to that described above for a single neuronal population with recurrent coupling, one obtains instead of Eq. 36 (Brunel and Wang 2003; Geisler et al. 2005; Ledoux and Brunel 2011):

$$\begin{aligned} & 1 - C_{II}J_{II}R_I(\omega)S_I(\omega) \\ & \times [1 - C_{EE}J_{EE}R_E(\omega)S_E(\omega)] \\ & = C_{EI}C_{IE}J_{EI}J_{IE}R_I(\omega)R_E(\omega)S_E(\omega)S_I(\omega), \end{aligned} \quad (40)$$

where $J_{EE} > 0$, $J_{II} < 0$, $J_{IE} > 0$, and $J_{EI} > 0$, respectively, measure the strength of the recurrent and mutual interactions between the excitatory (E) and inhibitory (I) populations. Instabilities and oscillations can be driven in networks of this kind by the recurrent inhibition between inhibitory interneurons, as in a single population, but also through a two-population inhibitory loop in which excitatory neurons drive inhibitory neurons which in return inhibit them. The frequency of the emergent oscillations therefore depends on the strength of the respective interactions.

In the case where the recurrent interactions within the populations can be neglected, taking the imaginary part of Eq. 40 gives the relation which determines the frequency of the oscillations in the network close to the instability threshold:

$$\begin{aligned} & \Phi_{RE}(\omega) + \Phi_{SE}(\omega) + \Phi_{RI}(\omega) + \Phi_{SI}(\omega) \\ & = \pi. \end{aligned} \quad (41)$$

The phases $\Phi_{RE}(\omega)$ and $\Phi_{RI}(\omega)$ are the phases of the firing-rate response of the excitatory (E) and inhibitory (I) neurons, and $\Phi_{SE}(\omega)$ and $\Phi_{SI}(\omega)$ the phase shift induced by excitatory (E) and inhibitory (I) synaptic transmission. When the synaptic phase shifts dominate, Eq. 41 reduces to

$$\Phi_{SE}(\omega) + \Phi_{SI}(\omega) = \pi. \quad (42)$$

Given that $\Phi_{SE} > 0$, this allows one to conclude that oscillations produced by the two-population loop are of lower frequency than those produced by the direct inhibition of interneurons among

themselves, as could intuitively be expected from the longer delay in the feedback inhibition. Typical values for the synaptic transmission kinetics lead one to expect that the 150–250 Hz frequency range of pure I-I inhibition-driven oscillation, as observed for the fast cerebellar observation, lowers to the 60 Hz gamma range for E-I driven oscillations.

In the general case, oscillations in the E-I networks can arise from a combination of the two outlined mechanisms. Examples of such population oscillations are illustrated in Fig. 3.

Population Density Model, Fig. 3 Different dynamical regimes of a sparsely connected neuronal network of excitatory and inhibitory leaky integrate-and-fire neurons. Central panel shows the boundaries of the region in which the asynchronous state is stable as a function of inhibition/excitation balance and external inputs. This region is confined to the inhibition-dominated network, in which mean inputs to neurons are below threshold due to the strong feedback inhibition and spiking is due to fluctuations. This asynchronous irregular (AI) state is therefore characterized by strongly irregular single-cell firing. The three solid lines are instability lines of the asynchronous state. Crossing these lines leads to three types of states in which the global population activity oscillates in time: a synchronous

irregular (SI) state with a fast population oscillation for strong inhibition and strong external inputs, a synchronous irregular (SI) state with slower population oscillations for lower external inputs, and finally, a synchronous regular (SR) state present when excitation dominates the feedback (Adapted from Brunel 2000a, b). Side panels indicate representative simulations in each of these four regions. Each pair of panels displays a raster plot of a subset of 50 neurons (spike times indicated by a vertical bar), and the global activity of the network, as a function of time. Note the large finite size effects, leading to strong fluctuations around the average rate in the AI state and to phase and amplitude fluctuations of the global oscillation in the SI states

Neurons with Heterogeneous Properties

We have described above how the population density approach can be used for two neuronal populations. It can further be generalized to multiple populations. This has in fact served to examine the dynamical consequence of the widely observed heterogeneity in neuronal populations. A heterogeneous population is viewed in this context as an assembly of different populations with continuously varying parameters which could, for instance, be the neuron firing frequencies or the synaptic properties. This is particularly important in the case of neural rhythms, since the synchronization of oscillators is well known to be strongly sensitive to heterogeneity and mismatch in frequencies. Neural rhythms which emerge from stochastically firing neurons are based on a quite different mechanism. It has been shown both in simulations and with population density analyses that, in contrast to classical oscillators, neural heterogeneity does not have a strong impact on the emergence of neural rhythms, although the threshold synaptic strength for their emergence does increase (Brunel and Hakim 1999).

Strong Coupling Regime

In vivo recordings show that neuron membrane potentials display strong fluctuations, as already emphasized. This has been taken into account in the above description by supposing that each neuron in the network is subjected to noise coming from external inputs to the network (as quantified, e.g., by σ_{ext} in Eq. 27). This does not appear fully satisfactory since, in a large network, part of the fluctuating inputs should arise from the drive coming from the neurons of the network themselves. It has been realized that this actually provides strong constraints on the network design (van Vreeswijk and Sompolinsky 1996; Amit and Brunel 1997). Let us consider a network with N_E excitatory neurons and N_I inhibitory neurons in which each neuron receives C_E excitatory and C_I inhibitory synapses from within the network as well as inputs from outside the network.

For simplicity, we first consider instantaneous synapses with weight J_E and $-J_I$, respectively, for excitatory and inhibitory synapses. We suppose that neurons fire in a Poissonian way, respectively, at rates v_E and v_I for the excitatory and inhibitory neurons and operate in the diffusion limit explained above (Eq. 4) where individual synaptic weights small but many inputs are received during the neuron integration time τ . In this case, neurons in the network receive a mean input,

$$\mu = [C_E J_E v_E - C_I J_I v_I] \tau + \mu_{ext} \quad (43)$$

with fluctuations of amplitude

$$\begin{aligned} \sigma^2 &= \sigma_{in}^2 + \sigma_{ext}^2 \text{ with } \sigma_{in}^2 \\ &= C_E J_E^2 v_E \tau + C_I J_I^2 v_I \tau, \end{aligned} \quad (44)$$

where the notations of Eq. 4 have been used. Neurons receive many synaptic contacts. In the previous sections, we have supposed that $J_E \sim 1/C_E$ and $J_I \sim 1/C_I$ so that the mean input μ remains finite in the limit where C_E and C_I are large. However, this implies also that the fluctuations of the network input are negligible ($\sigma_{in}^2 \sim 1/C$). Equation 44 shows that one should have the synaptic weights J of order $1/\sqrt{C}$ in order to have fluctuating internal inputs of finite amplitude. However, in this case, the mean input amplitude $|\mu|$ remains of reasonable amplitude only when the mean excitatory and inhibitory drives almost compensate each other, $C_E J_E v_E \sim C_I J_I v_I$, that is, when the network is in a so-called balanced state. This regime is naturally attained when the inhibition is sufficiently strong for the mean input current received by a neuron to remain under the threshold current required to induce spiking (van Vreeswijk and Sompolinsky 1996; Amit and Brunel 1997). Different experimental data indeed support the fact that neuronal networks work in this regime (Shu et al. 2003; Haider et al. 2006).

In the balanced state, the amplitude of the input fluctuations is not imposed but depends itself on the network state (since σ_{in} depends on the neuron firing rates). Within the framework of the

population density model, the network is described by an FPE like Eq. 30 in which σ^2 depends on the neuron firing rates and thus on time in a nonstationary dynamical regime. In the weakly coupled regime, the dynamics can be analyzed as previously described by the firing-rate response which characterizes the spiking output of a neuron subjected to a modulated current. This single function is no longer sufficient in the strong coupling regime and an equally important role is played to the firing response of a neuron to an oscillatory modulation of the noise amplitude in its input (Brunel and Hakim 1999; Brunel 2000b; Lindner and Schimansky-Geier 2001; Silberberg et al. 2004). While this allows one to extend the analysis to the strong coupling regime for instantaneous synapses, a precise analysis becomes much more involved for synapses with finite kinetics.

Deterministic Networks and the Population Density Approach

In recent years, a series of studies have investigated the dynamics of sparsely connected networks with no external noise (Zillmer et al. 2006, 2009; Jahnke et al. 2008, 2009; Monteforte and Wolf 2010, 2012). Interestingly, these networks typically exhibit highly irregular activity, in spite of the fact that the dynamics is purely deterministic. Zillmer et al. (2009) studied this phenomenon in networks of inhibitory LIF neurons with delta function synapses and found that the irregular dynamics is in fact a transient phenomenon. However, the duration of the transient dynamics increases exponentially with system size. This means that in practice, for realistic network sizes, the periodic attractor state is never reached. It was also found that the mean firing rate in such networks is well described by mean-field theory. Jahnke et al. (2008) showed analytically that any dynamical trajectory in such networks is stable. However, stability holds only for very small perturbations – any finite perturbations lead in the large N limit to a divergence between the perturbed and unperturbed trajectories. These phenomena are consistent with “stable

chaos” that was observed in coupled map lattices (Politi et al. 1993). Later studies showed however that adding a decay time constant of PSCs (Jahnke et al. 2009; Zillmer et al. 2009), excitatory neurons (Jahnke et al. 2009), or a more realistic spike generation mechanism (Monteforte and Wolf 2010) leads to truly chaotic dynamics. Therefore, chaotic dynamics seem to be the most common type of dynamics seen in deterministic randomly connected networks of excitatory and inhibitory neurons.

Conclusion

Population density methods have allowed theorists to characterize the dynamics of networks of simplified leaky integrate-and-fire neurons. In particular, these methods have uncovered different types of states in which these networks can settle: asynchronous states, in which the population firing rate is constant in time and correlations between neurons vanish in the large N limit, and synchronous states, in which population activity oscillates in time, with a frequency that can be related to synaptic and neuronal characteristics. The characteristics of these states bear striking similarities with in vivo recordings: asynchronous irregular states reproduce many of the landmark observations of background activity in the cortex (highly irregular activity of single neurons at low rates, wide distributions of firing rates, weak correlations between neurons), while synchronous irregular states share several characteristics of fast oscillations that are observed in many cortical areas.

So far, population density approaches have been limited to simplified single neuron models and highly simplified unstructured network architectures. Furthermore, even in these contexts, it has been mainly used to compute the stability boundaries of stationary regimes and the characteristics of the emerging oscillatory regimes at the linear or weakly nonlinear level. An important challenge for future years will be to extend this framework to more complex single neuron models, to more structured network architectures, and to fully nonlinear dynamical regimes.

Population Encoding/Decoding

Wilson Truccolo

Department of Neuroscience, Brown University, Providence, RI, USA

Definition

Sensory information, percepts, thoughts, and motor commands are thought to be carried out by spatiotemporal patterns of action potentials (spikes) in neuronal populations in the brain. Classical examples of neural encoding are the tuning of V1 neurons to oriented lines and the tuning of MT and M1 neurons to movement direction (Abbott and Dayan 2001). In addition, neural computation is thought to be instantiated by operations on these spatiotemporal spiking patterns. The problem of neural population encoding and decoding is addressed here from the perspective of reading out information about sensory stimuli and behavioral variables from spike trains simultaneously recorded from neuronal ensembles.

Detailed Description

Probabilistic Population Encoding and Decoding

Consider a sensory stimulus or behavioral variable (e.g., hand movement kinematics) $x_{1:t}$, during a discrete time period $\{1, 2, \dots, t\}$, $x_t \in \mathbb{R}^p$,

encoded by the spiking activity $y_{1:t} = \{y_{1:t}^i\}_{i=1}^N$ of N neurons; $y_t^i \in \{0, 1\}$ denotes whether the i th neuron has spiked or not in a small enough time interval of size Δ indexed by t . Given observed population spike trains $y_{1:t}$, what is the state x_t ? In the probabilistic Bayesian inference and stochastic state-space framework adopted here, this population decoding question is answered by computing the posterior probability density

$$\begin{aligned} p(x_t|y_{1:t}) &= \frac{p(y_{1:t}|x_t)}{\mathbb{P}(y_{1:t})} \\ &= \frac{\mathbb{P}(y_t|\mathcal{H}_t, x_t)p(x_t|\mathcal{H}_t)}{\mathbb{P}(y_t|\mathcal{H}_t)}, \end{aligned} \quad (1)$$

where $\mathbb{P}$ denotes probability and $\mathcal{H}_t = y_{1:t-1}$ is the population spiking history up to (but not including) time t . It is clear from Eq. 1 that the decoding problem $p(x_t|y_{1:t})$ is intrinsically related to a population encoding and neural dynamics model specified by $\mathbb{P}(y_t|\mathcal{H}_t, x_t)$. (For notational convenience, we let x and neuronal spiking to be instantaneously related.) We also note that the framework for population encoding/decoding adopted here can be extended to the broader problem of probabilistic inference and computation with spiking neuron networks.

Population Encoding and Neural Dynamics: $\mathbb{P}(y_t|\mathcal{H}_t, x_t)$

We assume that, conditioned on spiking history $\mathcal{H}_t$ and covariates x_t , the joint probability factorizes as

$$\mathbb{P}(y_t|\mathcal{H}_t, x_t) = \prod_{i=1}^N \mathbb{P}(y_t^i|\mathcal{H}_t, x_t). \quad (2)$$

The population encoding problem thus becomes the estimation of a probabilistic encoding model that captures both the intrinsic neural network dynamics (i.e., collective dynamics reflected in spiking history effects of the entire ensemble activity; Truccolo et al. (2010)) and the effects of x_t on the spiking probability for each observed single neuron. The encoding model can be expressed in terms of the conditional intensity function λ_t^i , i.e., the instantaneous spiking rate conditioned on

population spiking history $\mathcal{H}_t$ and on x_t , such that (Truccolo et al. 2005; Daley and Vere-Jones 2003)

$$\mathbb{P}(y_t^i | \mathcal{H}_t, x_t) = \exp \{ y_t^i \log (\lambda_t^i \Delta) - \lambda_t^i \Delta \} + o(\Delta), \quad (3)$$

where $o(\Delta)$ is a function satisfying $\lim_{\Delta \rightarrow 0} o(\Delta)/\Delta = 0$. Parametric and nonparametric models for the conditional intensity can be estimated from the data based on the discrete-time point process likelihood function derived from Eq. 3. The distribution in this case belongs to the exponential family with canonical parameter

$$\log (\lambda_t^i \Delta) = F_i(\mathcal{H}_t, x_t). \quad (4)$$

Simple but versatile approximations to $F_i(\mathcal{H}_t, x_t)$ can be obtained by generalized linear models (GLMs). For example, a conditional intensity function model for a primary motor cortex neuron that incorporates history effects and tuning to hand velocity x_t can be written as

$$\log (\lambda_t^i \Delta) = \mu_i + \sum_{j=1}^N \sum_{k=1}^q \alpha_k^{ij} y_{t-k}^j + \beta_i^T x_t, \quad (5)$$

where q specifies the extent of the history effects being taken into account and T denotes the transpose operation. Truccolo et al. (2005), Truccolo and Donoghue (2007), Truccolo (2010) provide a detailed treatment of parametric and nonparametric modeling of neural point processes based on and beyond GLMs. Effects of unobserved variables on spiking activity can be incorporated via latent variable models (e.g., Lawhern et al. (2010)), and violations of the assumed factorization in Eq. 2 due to unaccounted instantaneous correlations can be addressed according to Kelly and Kass (2012).

Population Decoding: $p(x_t | y_{1:t})$

In order to compute the posterior Eq. 1 recursively and to incorporate prior knowledge about the temporal evolution of x_t , a Markov state-space model

$$x_t \sim p(x_t | x_{t-1}), \quad (6)$$

$$y_t^i \sim \mathbb{P}(y_t^i | \mathcal{H}_t, x_t), \quad (7)$$

can be adopted. In this case, $p(x_t | \mathcal{H}_t)$ in Eq. 1 can be computed via the Chapman-Kolmogorov equation such that the posterior density then depends recursively on its previous step

$$p(x_t | y_{1:t}) = \frac{\mathbb{P}(y_t | \mathcal{H}_t, x_t)}{\mathbb{P}(y_t | \mathcal{H}_t)} \int p(x_t | x_{t-1}) p(x_{t-1} | y_{1:t-1}) dx_{t-1}. \quad (8)$$

Exact posterior computation can be attempted via numerical integration (for low-dimensional x_t) or via sequential Monte Carlo methods such as particle filters (Doucet et al. 2001). For practical applications, first- and second-order (fully exponential) Laplace approximations are very useful and can be easily implemented (Eden et al. 2004; Truccolo et al. 2005; Koyama et al. 2010). Consider the first-order Laplace approximation

$$p(x_t | y_{1:t}) \approx \mathcal{N}(x_{t|t}, W_{t|t}) \quad (9)$$

where

$$X_{t|t} = E[x_t | y_t, \mathcal{H}_t], \quad (10)$$

$$W_{t|t} = \text{var}[x_t | y_t, \mathcal{H}_t], \quad (11)$$

are the posterior mean and variance, respectively. Further, if the state transition probability $p(x_t | x_{t-1})$ is approximated according to an autoregressive process

$$x_t = Ax_{t-1} + \varepsilon_t, \quad (12)$$

where $\{\varepsilon_t\}$ are independent $\varepsilon_t \sim \mathcal{N}(0, Q)$, $x_0 \sim \mathcal{N}(\mu_0, W_0)$, then the posterior mean and variance under the Laplace approximation can be easily computed via the following stochastic state-space point process forward filter:

One-step prediction equations

$$x_{t|t-1} = Ax_{t-1|t-1}, \quad (13)$$

$$W_{t|t-1} = AW_{t-1|t-1}A^T + Q; \quad (14)$$

Population Encoding/Decoding, Fig. 1 Decoding of hand velocity from a population of monkey M1 neurons via the stochastic state-space point process filter. Decoded

hand velocities (horizontal and vertical coordinates) and decoded direction of the velocity vectors are shown in *red* (Modified with permission from Truccolo et al. (2005))

Posterior variance and mean equations

$$W_{t|t}^{-1} = W_{t|t-1}^{-1} + \sum_{i=1}^N \left[\left(\frac{\partial \log \lambda_t^i}{\partial x_t} \right)^T [\lambda_t^i \Delta] \left(\frac{\partial \log \lambda_t^i}{\partial x_t} \right) - (y_t^i - \lambda_t^i \Delta) \frac{\partial^2 \log \lambda_t^i}{\partial x_t \partial x_t^T} \right]_{x_{t|t-1}}, \quad (15)$$

$$x_{t|t} = x_{t|t-1} + W_{t|t} \sum_{i=1}^N \left[\left(\frac{\partial \log \lambda_t^i}{\partial x_t} \right)^T (y_t^i - \lambda_t^i \Delta) \right]_{x_{t|t-1}}. \quad (16)$$

Parameters for the state-space model can be estimated from a training dataset via maximum likelihood estimation related methods or, in the case of unobserved x_t , via expectation-maximization or other latent state-space estimation methods. Despite the Laplace approximation to the posterior, the point process nature of the observed spiking activity is preserved. Figure 1 provides a decoding example. Detailed derivations and extensions of the above stochastic

state-space point process filter for population decoding and other applications are presented in Eden et al. (2004), Truccolo (2010), Paninski et al. (2010), and Koyama et al. (2010).

Postinhibitory Rebound and Facilitation

Ramana Dodla

University of Texas at San Antonio, San Antonio, TX, USA

Definition

Postinhibitory rebound (PIR) and postinhibitory facilitation (PIF) are both phenomena that modify the intrinsic excitability of a neuron or a network resulting in an enhanced or patterned spike output. In a single neuron, the PIR represents evoking one or more spikes in response to the cessation of a prolonged hyperpolarizing current step. However, the response can also occur for a hyperpolarizing stimulus that is temporally brief. The PIF in a single neuron represents the phenomenon of evoking a spike when a late arriving subthreshold excitatory input is assisted by an early inhibitory input. The inhibitory input causes a reduction of spike threshold at the time of arrival of the subthreshold excitation.

Detailed Description

Rebound is a somewhat generic term that indicates the overshoot of a membrane potential above its resting level, and not necessarily a spike. The excitable property of an inhibitory stimulus applied to a neuron was identified more than a century ago by Sherrington (1913) who termed it “post-inhibitory exaltation” when a skeletal muscle showed spontaneous contractions at the cessation of a reflex inhibition. The term post-inhibitory rebound was coined by Granit (1956) and is often also termed rebound facilitation or anodal break response. In the modern usage, post-inhibitory rebound still represents the basic qualitative observations reported by Sherrington – eliciting a single or a group of spikes following the action of either a steady inhibitory current or a brief pulse of synaptic or current input. The PIR is responsible, for example, for setting up of

rhythmic pattern generation (Friesen 1994; Wang and Rinzel 1992) between neurons coupled with mutual inhibition.

The condition for eliciting PIR in a one-compartment neuron model is illustrated in Fig. 1a that shows the voltage $[V(t)]$ responses of the well-known Hodgkin-Huxley model, which rests at -60 mV in the absence of any input, to a step of hyperpolarizing current I_{app} . At the end of the hyperpolarizing current, if the release of the

current step is fast or instant, a spike is elicited; this is the PIR phenomenon. But if the release is gradual, only a brief overshoot of the membrane potential is seen, and not a spike. A spike might also be elicited even if the hyperpolarizing input pulse were very brief. Thus, a neuron may indeed have two thresholds for eliciting a spike, one for depolarizing current pulse and the other for hyperpolarizing current pulse. But in mathematical two-dimensional reduced models of neurons,

Postinhibitory Rebound and Facilitation,

Fig. 1 Demonstrating the eliciting of action potentials in a one-compartment Hodgkin-Huxley model by using postinhibitory rebound (a) and postinhibitory facilitation (b) mechanisms

these two thresholds could be seen as part of a single curve or manifold, which is called the threshold separatrix by FitzHugh (1955), whose placement around the rest state is curved and thus a neuron's ability to cross the threshold in eliciting a PIR spike depends on the response of the internal gating variables and the nature of the input itself (i.e., the magnitude and its time constant) (Dodla et al. 2006; Dodla and Wilson 2010). All neurons or neuronal models may not have the PIR property. Physiologically PIR may be realized under many different circumstances but could mainly be attributed to the deinactivation of a fast inward current or removal of the slow outward current (Jones and Thompson 2001). Examination of the time constants of the gating variables of the Hodgkin-Huxley model neuron reveals that, at hyperpolarized voltages, the activation and inactivation of sodium channel become faster while the potassium channel activation becomes even slower. Thus, upon sudden release from the hyperpolarizing step, the sodium channels have the ability to induce a spike before the action of the potassium channels. But a gradual release from the step (see Fig. 1a) will cause the potassium channels defeat the rush of sodium channels and prevent a spike.

Postinhibitory facilitation is closely related to the mechanism of the PIR and was first conceived to address the tuning curve asymmetry of auditory neurons (Dodla et al. 2006) that receive precisely timed but stochastic inhibitory and excitatory synaptic inputs (Brand et al. 2002). It can also be demonstrated in a variety of models including reduced two-dimensional models (Dodla et al. 2006; Dodla and Rinzel 2006). But this phenomenon is indeed related to the observation of modulating excitability of a neuron following an inhibitory stimulus (Luk and Aihara 2000) and the tighter temporal placement of action potentials when an inhibitory stimulus precedes an excitatory stimulus (Baufreton et al. 2005). At a single-neuron level, the PIF spike is elicited when a brief inhibitory stimulus precedes a brief subthreshold excitatory stimulus in a precise time window (Fig. 1b). If the excitatory stimulus arrives either too late or too early, the spike cannot

be elicited. The width of this facilitation window could be several milliseconds and depends on the decay time constant of the inhibitory input and the level of the subthreshold excitation. If the subthreshold excitation is close to the spike threshold, the window broadens significantly. But the neuron does not have to be a linear resonator (Izhikevich 2001), nor does the membrane voltage have to be near the closest approach to the spike threshold. Simulations reveal that facilitation is favored by fast inhibition (Dodla et al. 2006). Such fast but stochastic inhibitory stimuli when combined with stochastic excitatory stimuli could lead to an enhancement of firing rate (Dodla and Rinzel 2006) or even set coherent network oscillations in a mutually inhibitory network that is driven by random excitatory input.

Pre-Botzinger Complex Rhythm Generation

Natalia Toporikova
Department of Biology, Washington and Lee University, Lexington, VA, USA

Definition

The pre-Botzinger complex (preBötC) in mammals is a small area of the ventrolateral medulla which generates stable neuronal rhythmic output in phase with the inspiratory muscles of the diaphragm. This rhythmic activity is generated in isolation from the rest of the respiratory column by approximately a thousand bilaterally distributed neurons. Damage to the preBötC results in an inability to breathe and eventual death.

Detailed Description

Respiration is a physiological process of supplying tissues with oxygen and removing carbon dioxide. In mammals, expansion and contraction

of the lungs provide movement of air between the atmosphere and lung alveoli, where oxygen is exchanged with carbon dioxide. Coordinated movements of the diaphragm muscles generate the regular breathing pattern. First, contraction of the muscles during the inspiratory movement pulls the lower surfaces of the lung downward. Then, during expiration, the diaphragm relaxes and abdominal structures compress the lungs. Rhythmic contraction and relaxation of the muscles of the diaphragm during breathing is controlled by neuronal signals from the several areas of the brain stem. The minimal neural structure whose neural output is correlated with the contraction of inspiratory muscles is a small area of the ventrolateral medulla, called the pre-Botzinger complex (preBötC).

The important role of the preBötC in inspiratory rhythm generation was established in a series of experiments by Smith and colleagues (Smith et al. 1991). By extracting parts of the respiratory column, they discovered that removal of the preBötC results in complete cessation of rhythmic activity. When the preBötC is isolated in a brain stem slice preparation (Fig. 1a), it generates rhythmic neuronal activity in phase with the activity of inspiratory motoneurons (Fig. 1b).

Rhythmic activity in the preBötC depends on excitatory synaptic connections between the neurons, because blocking excitatory synapses ceases the inspiratory rhythm (Fig. 1c). However, some of the preBötC neurons (5–20%) remain rhythmic in isolation (Del Negro et al. 2005; Mellen and Mishra 2010). The role of intrinsically bursting neurons, known as *endogenous bursters* or *pacemakers*, is a hotly debated topic and there have been a number of theories proposed over the years about their role in respiratory rhythm generation.

Two endogenous bursting mechanisms have been described in preBötC neurons (Thoby-Brisson and Ramirez 2001). One type of bursting is mediated by Ca^{2+} (Fig. 2a) and therefore can be suppressed by the application of cadmium (Cd, which is a blocker of a wide range of Ca^{2+} channels.) This type of endogenous bursting neuron is often referred to as a *Cd-sensitive pacemaker*, *Ca-sensitive burster*, or *calcium burster*. Later it was shown that the calcium dependence in this

Pre-Bötzinger Complex Rhythm Generation,

Fig. 1 Experimental model and intracellular recordings from a typical inspiratory neuron. (a) Schematic representation of a brain stem slice preparation obtained from mice. This slice contains the pre-Bötzinger complex (PBC) (b and c) extracellular population activity from the PBC recorded and integrated (PBC int: integrated traces) with simultaneous intracellular recording obtained from an inspiratory neuron under control conditions (b) and after blockade of glutamatergic synapses with 20 μ M of (CNQX, c). Depolarizing current injections (*top*: 0.4 nA; *bottom*: 1 nA) did not trigger bursting activity in the neuron in CNQX (Thoby-Brisson and Ramirez 2001, Fig. 1. Reprinted with permission)

endogenous burster was associated with a calcium-activated nonspecific cationic current (I_{CaN}) (Peña et al. 2004; Del Negro et al. 2005). The second type of endogenous burster remains rhythmic in the presence Cd but ceases its rhythmic output in the presence of any blocker of the persistent sodium current (Fig. 2b). This type of bursting neuron is often called a *Cd-insensitive pacemaker*, *Ca²⁺-insensitive burster*, or *persistent Na⁺ burster*.

Over the last 20+ years, a number of models have been proposed to understand the rhythmic activity of the preBötC and more specifically the endogenous bursting of individual preBötC

neurons. In this entry, four models of preBötC rhythmic activity generation will be discussed chronologically. For convenience, the models will be referred by the name of the first author and the year of first publication.

Persistent Na⁺ Bursting Mechanism (Butera 1999 Model)

After the original identification of endogenous bursters, the ionic mechanism underlying rhythmic electrical activity of preBötC neurons remained unknown. To identify a potential mechanism for

Pre-Botzinger Complex Rhythm Generation, Table 1 Equations for Butera model

Variable	Equations	Eq. #
Voltage across the cell membrane	$C_m \frac{dV}{dt} = -I_{Na} - I_{NaP} - I_K - I_L - I_{ton} - I_{syn}$	1
Activation of fast Na ⁺ current	$\frac{dn}{dt} = \frac{n_{\infty}(V) - n}{\tau_n(V)}$	2
Inactivation of persistent Na ⁺ current	$\frac{dh}{dt} = \frac{h_{\infty}(V) - h}{\tau_h(V)}$	3
Synaptic activity	$\frac{ds}{dt} = \frac{(1-s)s_{\infty} - k_{syn}n}{\tau_s(V)}$	4

intrinsic bursting, Butera and colleagues published a mathematical model (Tables 1, 2, and 3) proposing inactivation of a persistent Na⁺ current as an intrinsic burst mechanism (Butera et al. 1999b). Comparing the model with experiments, the authors concluded that the persistent Na⁺ bursting mechanism is compatible with experimental data. Later, this model was confirmed by electrophysiological experiments. The range of values for the conductances of the persistent Na⁺ current (g_{NaP}) was measured in later experiments (Purvis et al. 2007).

The model contains the essential spiking currents: fast inward Na⁺ (I_{Na}), outward delayed rectifying K⁺ (I_K), persistent Na⁺ current (I_{NaP}), and passive leak (I_{leak}). Since inactivation of persistent sodium is several orders of magnitude slower than other currents, its slow decrease provides burst termination mechanism.

The Single Cell Model

The Butera 1999 model (Fig. 3) consists of a fast inward Na⁺ (I_{Na}), an outward delayed rectifying K⁺ (I_K), persistent Na⁺ (I_{NaP}), and passive leak

Pre-Botzinger Complex Rhythm Generation, Table 2 Equations for current in Butera 1999 model. The parameter g represents the maximal conductance of

the appropriate current (Na , NaP , K , $Leak$, or $tonic$), while n and h are activation and inactivation variables, respectively

Current	Equations	Eq. #
Inward fast Na^+	$I_{Na} = g_{Na} m \infty^3 (1 - n)(V - V_{Na})$	5
Persistent Na^+	$I_{NaP} = g_{NaP} p \infty h(V - V_{Na})$	6

Pre-Botzinger Complex Rhythm Generation, Fig. 3 Schematic diagram of Butera 1999 model. (a) Diagram of ionic current in the model. (b) The bursting dynamics in the model depend on inactivation of persistent sodium current (I_{NaP}). When the membrane voltage

reaches its threshold, a series of action potentials are generated by a fast sodium current (I_{Na}) and a delayed rectifier potassium current (I_K). The burst is then terminated by the slow inactivation of I_{NaP}

(I_{leak}) currents. The bursting in the model depends on the inactivation dynamics of the persistent Na^+ current. When I_{NaP} is fully de-inactivated, the cell is above the spiking threshold and action potentials are produced through the interaction of I_{Na} and I_K . Since the time constant of persistent Na^+ is

significantly higher than the time constant of fast Na^+ current (Fig. 4, low panel), I_{NaP} slowly inactivates during the burst (Fig. 3b, red trace) and repolarizes the cell below the spiking threshold. The frequency and duration of the burst are regulated by the maximum value of the persistent

Pre-Botzinger Complex Rhythm Generation,

Fig. 4 Gating characteristics of components of Butera 1999 model. *Top panel:* activation/inactivation curves. *Bottom panel:* voltage-dependent time constants for fast and persistent sodium currents

Na⁺ conductance (g_{NaP}). If g_{NaP} is low (Fig. 5, top panel), the cell remains below the spiking threshold with constant membrane potential. An increase in g_{NaP} depolarizes the cell above the spiking threshold and induces bursting (Fig. 5, two middle panels). The frequency and duration of the bursting depend on the g_{NaP} (compare two middle panels in Fig. 5). Further increase in g_{NaP} leads to continuous spiking (Fig. 5, bottom panel).

However, the effect of g_{NaP} depends on the overall excitability of the preBötC network, which can be altered by the concentrations of extracellular ions or by application of excitatory neuromodulators. In vivo experiments in preBötC brain stem slices demonstrated that the frequency of bursting depends on K⁺ concentration. Reducing K⁺ decreases the burst frequency, and conversely, raising K⁺ increases the burst frequency. Since leak current in preBötC is carried out mostly by K⁺ ions, the application of K⁺ in Butera 1999 model can be simulated by manipulation of reversal potential for the leak current (V_L), with more hyperpolarized V_L representing low K⁺ concentration and more depolarized V_L representing high K⁺. The model reproduces

experimental data on K⁺ application with a higher level of V_L increasing the burst frequency and lower level of V_L decreasing burst frequency (Butera et al. 1999b).

The model predicts that the combination of excitability (V_L) and persistent Na⁺ conductance (g_{NaP}) determines the pattern of electrical activity in a model cell (Fig. 6). For low excitability (low V_L), a progressive increase in g_{NaP} induces a transition from silence to bursting to tonic firing (Fig. 6). In highly excitable conditions (high V_L), no bursting behavior can be achieved and increase in g_{NaP} induces a transition from silence directly to tonic firing (Fig. 6, $V_L > -56$ mV). The prediction that the combination of excitability and persistent Na⁺ conductance determines the degree of bursting was later confirmed experimentally (Purvis et al. 2007).

The Network Model

The preBötC generates rhythmic output only if excitatory synaptic connections among the preBötC neurons are intact; experimentally, it is found that blocking excitatory connections completely abolish the preBötC rhythm. In

Pre-Botzinger Complex Rhythm Generation,

Fig. 5 Conductance of persistent sodium current guides transition from silence to bursting and then to tonic spiking. (a) For low values of g_{NaP} the model cell is silent. (b) Increase in g_{NaP} induces transition from silence to bursting. (c) Increase in g_{NaP} increases both burst frequency and burst duration. (d) Further increase in g_{NaP} induces transition from bursting to tonic spiking

Pre-Botzinger Complex Rhythm Generation,

Fig. 6 Intrinsic modes of single-cell activity in Butera model as a function of g_{NaP} and V_L (Butera et al. 1999a, Fig. 7. Reprinted with permission)

addition, tonic excitatory input to the preBötC, provided by excitatory neuromodulators, modifies the rhythmic output of the network. The effects of synaptic excitatory connections and tonic drive on a network constructed from Butera 1999 model

neurons were studied in networks of different sizes (Butera et al. 1999b).

A pair of bursting neurons generates a stable synchronous bursting rhythm when connected through excitatory synapses. The combination of

Pre-Botzinger Complex Rhythm Generation, Fig. 7 Effects of g_{tonic} and g_{syn} on the dynamics of bursting and beating of pairs of coupled cells. Plots are of burst duration (a), burst interval (b), and burst period (c). Colored areas indicate regions of dynamic activity being quantified. The range of shaded values for each diagram is indicated by the associated range bar for each figure.

Units are indicated at the top of each range bar. Color values were scaled to parameter ranges that most accurately revealed trends in the data, and values beyond the minimum or maximum of the range of values used for coloring were clipped at those values (Butera et al. 1999b, Fig. 2. Reprinted with permission)

excitatory synaptic coupling and tonic drive determines the mode of activity (silence, bursting, or tonic). An increase in synaptic coupling increases the burst duration, burst interval, and burst period; however, this effect depends on the tonic drive (Fig. 7). The range of synaptic strengths for which rhythmic output can be achieved is narrowed with larger excitatory tonic drive. These findings are also observed in larger networks of bursting neurons.

However, intrinsically bursting cells constitute only a small fraction of preBötC neurons: a large portion of the neurons are either silent or tonic (note: tonic may also be referred to as *spiking* or *beating*). A realistic distribution of intrinsic firing properties in the Butera 1999 model can be achieved by assigning a distribution of g_{NaP} values (Fig. 6). In a heterogeneous network of silent, bursting, and tonic cells, coupling the cells through excitatory synaptic connections induces rhythmic network output similar to experimental recordings of the preBötC mean field potential. This rhythm disappears if the strength of the excitatory connections is reduced. The network model predicts that the combination of excitatory synaptic coupling and common tonic drive accounts for the synchronization, frequency control, patterns of inspiratory cell activity,

synaptic interactions, and network activity found in vitro (Fig. 8).

Bursting Mechanism Based on I_{CaN} and Na/K Pumps (Rubin 2009 Model)

Since intrinsic bursters are rare in the preBötC (Del Negro et al. 2005), it has been hypothesized that rhythmic output does not rely on intrinsic neuronal activity, but is a result of emergent network properties. This theory, called the *group-pacemaker hypothesis*, stated that periodic inspiratory bursts are generated by intrinsic currents, which are dormant in isolated cells, but activated by synaptic activity (Rekling and Feldman 1998; Mironov 2008; Del Negro and Hayes 2008). Ca^{2+} -activated nonspecific cation current (I_{CaN}) is one potential candidate to satisfy the group-pacemaker hypothesis. Activated by the stimulation of postsynaptic metabotropic glutamate receptors (mGluRs), I_{CaN} produces a depolarizing burst potential in preBötC neurons (Pace et al. 2007).

To explore a rhythmogenic mechanism based on the group-pacemaker hypothesis, Rubin and colleagues (Rubin et al. 2009) proposed a preBötC rhythm generation model

Pre-Botzinger Complex Rhythm Generation,

Fig. 8 Effects of excitatory coupling on synchronization of a heterogeneous population of 50 bursting neurons. Raster plots illustrate spike times of the population of the 50 cells before (**A1**) and after (**B1**) coupling. Network activity (**A2** and **B2**) is defined by calculating histograms of spike times across the population (bin size: 510 ms). *Bar plots* illustrate the number of cells in a population whose dynamics are defined as silent, bursting, or beating before (**A3**) and after (**B3**) coupling. Results are pooled from 50 simulations (Butera et al. 1999b, Fig. 3. Reprinted with permission)

Na^+ concentration	$\frac{d[Na]}{dt} = \alpha(-I_{CaN} - I_{pump})$	14
Intracellular Ca^{2+} concentration	$\frac{d[Ca]}{dt} = \varepsilon([IP_3]s - K_{Ca}([Ca] - [Ca]_{\infty}))$	15
Synaptic activity	Same as Butera 1999	4

(Tables 4, 5, and 6) based on activation of I_{CaN} by synaptic activity (Fig. 9). It has been shown experimentally that activation of synaptic AMPA receptors by glutamate triggers a small influx of calcium (Pace and Del Negro 2008). In addition, glutamate binding to mGluRs can induce G protein activation that leads to synthesis of inositol 1,4,5-trisphosphate (IP_3) and subsequent

release of intracellular Ca^{2+} . In both cases, an increase in intracellular Ca^{2+} activates I_{CaN} (Pace et al. 2007).

The Single Self-Coupled Model

Although the authors conducted the majority of their analysis in one model neuron, the model is self-coupled and therefore represents the activity of

Pre-Botzinger Complex Rhythm Generation, Table 5 Currents of Rubin 2009 model. The component of modified Rubin 2009 model is highlighted in gray

a small, synaptically coupled network. In the model, recurrent synaptic excitation stimulates I_{CaN} by activation of IP₃-dependent release of intracellular Ca²⁺ (Fig. 10, top and middle panels). Depolarization due to I_{CaN} also causes voltage-dependent spike inactivation (*depolarizing block*), which reduces synaptic excitation and thus decreases postsynaptic Ca²⁺ accumulation. The influx of Na⁺, through the ion channel associated with I_{CaN} , stimulates the activity of Na/K pumps, repolarizing the cell and terminating the burst (Fig. 10, bottom panel). The recovery of spiking activity initiates a new burst cycle. Since in this case, (i) a synaptic input activates a postsynaptic burst-generating conductance (namely, I_{CaN}) and (ii) the rhythm generation depends on synaptic components rather than on endogenous bursting components, this rhythm-generating mechanism fits the *group-pacemaker* hypothesis.

The disadvantage of the original Rubin 2009 model was its limited implementation of I_{NaP} . Since I_{NaP} was identified in the majority of pre-BötC neurons (Del Negro et al. 2001; Purvis et al. 2007), it is likely that the interaction of I_{NaP} and

Pre-Botzinger Complex Rhythm Generation, Fig. 9 Schematic diagram of Rubin 2009 model. Self-coupled model neurons have a spike-generating mechanism consisting of fast Na + (I_{Na}), delayed rectifier K + (I_K), and leak (I_L) currents. Synaptic activity of the cell stimulates mGluR and releases intracellular Ca²⁺, which activates I_{CaN} . The influx of Na + through I_{CaN} activates an outward current mediated by Na/K ATPase (I_{pump}). Interaction of I_{NaP} and I_{CaN} was included in a modified model, which is indicated in *red dashed outline*

I_{CaN} produces the cellular activity that underlies the bursting rhythm. The model was modified (Dunmyre et al. 2011), and the combined effect of I_{NaP} and I_{CaN} was analyzed by varying their conductances. It has been found that the modified model exhibits a variety of activity patterns, including quiescence, tonic activity, square-wave bursting, depolarized bursting, and a mixture of square-wave and depolarized bursting, which matches well with the activity observed in experimental preparations (Fig. 11).

Pre-Botzinger Complex Rhythm Generation,

Fig. 10 Bursting in the model in Rubin 2009 model. The burst is initiated by depolarizing spiking currents (*top panel*). The depolarizing block during the burst is a result of increase in I_{CaN} (*middle trace*). The activation of Na/K pumps by increase in Na⁺ concentration (*bottom panel*) terminates the burst

Bursting Mechanism Based on Ca^{2+} Oscillations (Toporikova 2011 Model)

The frequency of breathing is controlled by the release of neuromodulators (often referred to as the *neuromodulatory tone*). In preBötC, the neuromodulatory tone is predominantly excitatory, through release of substance P (SP), serotonin (5-HT), norepinephrine (NA), and other neuromodulators. Some of these, such as SP and 5-HT, are released from the nearby Raphe nucleus which is preserved in a brain slice preparation. Although application of these neuromodulators in vitro excites activity of individual preBötC neurons, the extent of this effect varies from neuron to neuron. Some neuromodulators dynamically modulate the intrinsic properties of preBötC neurons and convert non-bursting cells into endogenous bursters. For example, it has been found that application of 5-HT can induce intrinsic bursting activity in non-bursting inspiratory neurons (Peña et al. 2004; Ptak et al. 2009). However, the same neuromodulator can have a different effect on Ca-sensitive and Ca-insensitive bursters (Ben-Mabrouk and Tryba 2010; Peña and Ramirez 2004). Interestingly, a large fraction of excitatory neuromodulators in the preBötC activate receptors coupled to the Gq protein pathway.

To reconcile the existence of two different types of intrinsic bursters and include the effect of neuromodulators on different cell types in the preBötC, the Toporikova 2011 model was proposed (Tables 7, 8, and 9). The authors hypothesized that Ca-dependent bursting was a result of rhythmic Ca^{2+} release from the endoplasmic reticulum (ER), the cell's Ca^{2+} store (Fig. 12). Depending on the capacity of the intracellular Ca^{2+} store and the value of the persistent Na^+ conductance, the model can reproduce Ca-dependent and/or Ca-independent bursting. The model also can reproduce dynamic changes in intrinsic cell properties during the application of neuromodulators (Toporikova and Butera 2011).

The Single Cell Model

The Toporikova 2011 model neuron has somatic and dendritic compartments, connected through an axial resistance. For the somatic compartment, the authors used a Butera 1999 model. The model hypothesizes that Ca^{2+} oscillations occur in the dendritic compartment (Mironov 2008). The neuromodulator binds to a G_q -coupled receptor and activates release of IP_3 , which binds to its receptor on the surface of the ER and induces Ca^{2+} release from the ER. The resulting increase in Ca^{2+} activates I_{CaN} and depolarizes the dendrite. The depolarizing potential then moves to

Pre-Botzinger Complex Rhythm Generation,

Fig. 11 Partition of (g_{NaP}, g_{CaN}) parameter space based on the dynamics of the unified model. *Blue dots* represent quiescent solutions. *Black dots* represent tonic activity. *Green dots* represent bursting activity, either of depolarized block bursting or square-wave bursting type. Panel (a) corresponds to region II, (b) to region III, and (c) to region*, while panel (d) shows the typical structure of a depolarized block burst from region III or region*. Panel (e) shows activity from region V, (f) from region IV, and (g) from region VI (Dunmyre et al. 2011. Reproduced with permission)

the soma where it activates essential spiking currents. The flux of Ca^{2+} from the ER into the cytosol is regulated by the activity of the IP_3 receptor. The flux from the cytosol back to the ER is controlled by the activity of ATPase SERCA pumps.

The Ca-sensitive and Ca-insensitive bursting types in the Toporikova 2011 model are characterized by different values of the parameters $[Ca]_{tot}$ and g_{NaP} (Fig. 13). The parameter $[Ca]_{tot}$ represents the capacity of the ER (for Ca^{2+} storage) and is determined by dendritic morphology.

Pre-Botzinger Complex Rhythm Generation, Table 7 Equations of Toporikova 2011 model. The components of the network model (Toporikova and Butera 2013) are highlighted in gray

Variable	Equations	Eq. #
Somatic voltage	$C_m S \frac{dV_s}{dt} = -I_{Na} - I_{NaP} - I_K - I_K - I_{DS} - I_{syn}$	3.1

Persistent Na ⁺	Same as Butera 1999	1.6
Delayed rectifying K ⁺	Same as Butera 1999	1.7
Leak	Same as Butera 1999	1.8
Somato-dendritic	$I_{SD} = \frac{g_c}{k}(V_D - V_S)$	3.6
Dendrito-somatic	$I_{DS} = \frac{g_c}{1-k}(V_D - V_S)$	3.7
Ca ²⁺ -activated nonspecific cation current	$I_{CaN} = g_{CaN} \frac{V_D - V_{Na}}{1 + \frac{K_{CaN}}{[Ca]}}$	3.8
Synaptic current	Same as Butera 1999	1.10

The model can reproduce the experiments on application of blockers of either I_{CaN} or I_{NaP}. If there are no Ca²⁺ oscillations and persistent Na⁺ is in the bursting range, the bursting is Ca-insensitive (Fig. 12a, green star). The bursting activity in this regime is prevented by blocking I_{NaP}; however, blocking Ca²⁺ does not affect the rhythmic activity (Fig. 13b). When Ca²⁺ is in the oscillatory regime, but g_{NaP} is in the sub-oscillatory range, the bursting is Ca-sensitive (Fig. 13a, blue star). The bursting activity in this regime is prevented by blocking Ca²⁺; however, blocking I_{NaP} does not affect the rhythmic activity (Fig. 12d). Lastly, when both g_{NaP} and [Ca]_{tot} are in the bursting regime (Fig. 13a, red star), the bursting is insensitive to blocking either I_{NaP} or Ca²⁺ (Fig. 13c).

Pre-Botzinger Complex Rhythm Generation, Table 9 Equations of Toporikova 2011 model. The components of the network model (Toporikova and Butera 2013) are highlighted in gray

Function	Equations	Eq. #
Activation/inactivation function	Same as Butera 1999	1.11
Voltage dependent time constant	Same as Butera 1999	1.12
Flux of Ca ²⁺ from ER into the cytosol	$J_{ERIN} = (L_{IP3R} + P_{IP3R}\alpha^3)([Ca]_{ER} - [Ca])$	3.9
IP ₃ R gating function	$\alpha = \frac{[IP3][Ca]}{([IP3] + K_i)([Ca] + K_a)}$	3.10
Flux of Ca ²⁺ from the cytosol the ER	$J_{EROUT} = V_{SERCA} \frac{[Ca]^2}{K_{SERCA}^2 + [Ca]^2}$	3.11
ER Ca ²⁺ concentration	$[Ca]_{ER} = \frac{[Ca]_{tot} - [Ca]}{\sigma}$	3.12
IP ₃ concentration	$[IP3] = \alpha[NT]$	3.13

Calcium oscillations in the two-compartment model also depend on the concentration of bath-applied excitatory neuromodulators, which activate the G_q protein pathway and induce IP₃ release. The variable [NT] in the model represents the concentration of such neuromodulators, presumably SP or 5-HT. The authors investigated electrical activity in the model to show that the presence of Ca²⁺ oscillations is nonlinearly dependent on the values of [NT] and [Ca]_{tot} (Fig. 14a). For example, Ca²⁺ oscillations in the model can be generated at low levels of [Ca]_{tot}, if

Pre-Botzinger Complex Rhythm Generation, Fig. 12 Schematic diagram of Toporikova 2011 model. The bursting mechanism in somatic compartment is based on persistent sodium current inactivation, while dendritic compartment does not have its own spike-generating currents. Instead, dendritic compartment produces a depolarizing potential following intracellular Ca^{2+} oscillations. An increase in the intracellular Ca^{2+} concentration activates I_{CaN} and depolarizes the cell. When the Ca^{2+} concentration decreases, I_{CaN} inactivates and the cell repolarizes to its resting potential. Calcium oscillations in our

model are dependent on neuromodulator (NT) binding to Gq-protein-coupled receptor. The activation of Gq-protein-coupled receptors leads to an increase in $[\text{IP}_3]$, which binds to its receptor (IP_3R) on the surface of the endoplasmic reticulum (ER) and initiates a Ca^{2+} flux into the cytosol. This Ca^{2+} flux is terminated by the slow inactivation of IP_3R by Ca^{2+} . As a result, intracellular Ca^{2+} decreases as the SERCA pumps bring Ca^{2+} back to the ER. This cycle repeats as IP_3R inactivation is removed at low Ca^{2+} concentration

Pre-Botzinger Complex Rhythm Generation, Fig. 13 The type of endogenous bursting activity is determined by values of parameters for persistent sodium conductance (g_{NaP}) and total amount of ER Ca^{2+} . (a) The range of parameters for different types of electrical activity in the model. White color represents tonic spiking, light gray is silence, and dark gray is bursting. The bursting regime is divided into Ca-sensitive, Ca-insensitive, and mixed types. Stars show representative values chosen for simulations

(b) sub-oscillatory Ca^{2+} regime and g_{NaP} in bursting regime (green star in panel a); the model cell is rhythmic if I_{NaP} is blocked, but blocking of I_{CaN} eliminates bursting. (c) When Ca^{2+} is in the oscillatory regime and g_{NaP} is above the bursting threshold (red star in panel a), the cell produces bursting if either I_{NaP} or I_{CaN} is blocked. (d) If Ca is in oscillatory regime but g_{NaP} is below bursting threshold (blue star in panel a), the model cell remains rhythmic when I_{CaN} is blocked, but bursting ceases if I_{NaP} is blocked

Pre-Botzinger Complex Rhythm Generation, Fig. 14 Bursting in the two-compartment model depends on the choice of parameters. (a) Dendritic bursting regime depends on neuromodulatory tone, $[NT]$, and total Ca^{2+}

concentration in the ER ($[Ca]_{tot}$). (b) A fraction of Ca -dependent bursters in heterogeneous population of cells increases with increase in neuromodulatory tone

$[NT]$ is sufficiently large. These results are consistent with the experimental data on inducing bursting activity in non-bursting inspiratory neurons by application of 5-HT (Peña and Ramirez 2004; Ptak et al. 2009). As a result, the model predicts that in a population of cells with a heterogeneous distribution of bursting properties, the application of excitatory neuromodulators increases the fraction of Ca -sensitive endogenous bursters (Fig. 14b).

The Network Model

Although the Toporikova 2011 single cell model explains the coexistence of two types of intrinsic bursting in the preBötC cell, it can generate a stable network rhythm only in a very narrow range of neuromodulatory tones. This can be contrasted with an *in vivo* respiratory network, which generates a stable rhythm in a wide range of neuromodulatory tones. To determine the condition for stable rhythm generation in a network with a realistic distribution of intrinsic properties, the authors investigated different connectivities between the preBötC and the Raphe nucleus, which produces a large fraction of the neuromodulators affecting the respiratory rhythm

(Toporikova and Butera 2013). It has been found that a network which includes positive feedback between the Raphe nucleus and the preBötC can produce stable rhythmic output in a wide range of neuromodulatory tones (Fig. 15g). The model also predicts that a brief increase in the release of neuromodulators by the Raphe nucleus induces simultaneous Ca^{2+} oscillations in preBötC neurons (Fig. 15a–f).

Bursting Mechanism Based on Combination of Persistent Na^+ , Na/K Pumps, and Ca^{2+} (Jasinski 2013 Model)

Although experimental studies in rodent brain stem slices containing the preBötC identified that both I_{CaN} and I_{NaP} potentially contribute to the generation of the rhythm, the contribution of each of these mechanisms to rhythmic bursting remains unresolved. The model of Jasinski et al. 2013 (Tables 10, 11, and 12) evaluates the roles of intrinsic Na^+ -dependent and Ca^{2+} -dependent bursting in the generation of rhythmic activity in preBötC (Jasinski et al. 2013). The model explicitly simulates several aspects of the neuron

Pre-Botzinger Complex Rhythm Generation, Fig. 15 Effect of neuromodulatory tone on frequency modulation in a 50-cell network with positive feedback between preBötC and Raphe. The strength of positive feedback is represented by parameter K_{phasic} . The neuromodulatory tone is represented by a parameter K_{tonic} . (a–c) A raster plot of a representative network simulation with positive feedback ($K_{phasic} = 15$). Network frequency increases with an increase in neuromodulatory tone. (a) In low ($K_{tonic} = 0.4$) neuromodulatory tone, the frequency is low. (b) In medium ($K_{tonic} = 1$) neuromodulatory tone, the frequency increases. (c) In high neuromodulatory tone

($K_{tonic} = 1.6$), the burst frequency increases further and the burst shape remains representative of preBötC neurons. (d–f) Concentration of excitatory neuromodulator ([NT]) in the same simulations as (a–c). The rise in [NT] coincides with increases in spiking activity of the network. (g) Burst frequency responses to neuromodulatory tone for four different strengths of positive feedback (K_{phasic}). The network with strong connection between preBötC and Raphe ($K_{phasic} = 15$, blue trace) shows the largest range of frequencies in response to progressive increase in neuromodulatory tone

Pre-Botzinger Complex Rhythm Generation, Fig. 16 Schematic diagram of Jasinski 2013 model.

The model has essential spiking currents (I_{Na} , I_K , and I_L), essential bursting currents (I_{CaN} and I_{NaP}), and balance of Ca^{2+} and Na^+ ions. Depending on choice of parameters for conductances of persistent sodium current (g_{NaP}) and voltage-gated Ca^{2+} current (g_{Ca}), the model can reproduce Ca-dependent or Ca-independent (NaP) bursting. Combination of Ca^{2+} influx through voltage-gated Ca^{2+} channels and activation Ca^{2+} release through IP_3 -dependent pathway, mediates Ca-dependent bursting in the model. The Ca-dependent burst can be terminated by either inactivation of IP_3R by Ca^{2+} or by activity of Na/K pumps by the influx of Na through ICaN

dynamics, synaptic interactions, ionotropic and metabotropic synaptic mechanisms, intracellular Ca^{2+} release, and the Na/K pump and examines their effects on network rhythmic bursting. The model predicts that the rhythmic preBötC activity is state-dependent and can operate in either an I_{NaP} -dependent regime or an I_{CaN} -dependent regime or both (Fig. 16).

The Single Cell Model

The goal of the model is to explore the effect of Na^+ - and Ca^{2+} -dependent bursting mechanisms at different levels of the tonic drive. The single cell model includes essential spiking currents as well as balanced equations for Na^+ and Ca^{2+} . The Ca^{2+} can either be released from the ER or enter through a voltage-gated Ca^{2+} channel during the

action potential. The authors explored the two different mechanisms for Ca-dependent bursting. The first mechanism is based on Ca^{2+} oscillations (similar to Toporikova 2011) with burst termination through inactivation of IP_3R by Ca^{2+} . The second mechanism is based on Ca^{2+} entrance through voltage-gated Ca^{2+} channels; in this case, the burst is terminated through the activity of Na/K pumps induced by I_{CaN} (similar to Rubin

Pre-Botzinger Complex Rhythm Generation, Fig. 17 Simulation of I_{Ca} -dependent and I_{CaN} -dependent bursting by the use of two single-neuron models with different burst-terminating mechanisms. In the first model (a), burst termination was based on Ca^{2+} -dependent IP3R inactivation (see the traces for IP3R gating variable I and

$[Ca^{2+}]_{in}$). In the second model (b), there were two burst-terminating mechanisms: one based on Ca^{2+} -dependent IP3R inactivation (as in the first model) and the other based on intracellular Na^+ accumulation (see $[Na^+]_{in}$ in traces) and subsequent activation of the Na/K pump (Jasinski et al. 2013, Fig. 3. Reprinted with permission)

2009). The authors refer to these two Ca^{2+} mechanism as I_{Ca} -dependent and I_{CaN} -dependent, respectively (Fig. 17). It was found that the distribution of parameters determines the type of bursting in a given cell and also that the bursting mechanisms can dynamically change with the applied tonic drive. Such a mechanism would be beneficial for a preBötC network, where

neuromodulatory tone and input from other brain areas change dramatically within short time intervals.

The Network Model

The authors also simulated a network of excitatory-connected neurons by hypothesizing a heterogeneous distribution of synaptic weights

Pre-Botzinger Complex Rhythm Generation, Fig. 18 Synaptic excitability and tonic drive can modulate the type of bursting in the model network. The region for I_{NaP} -dependent population bursting is shown in blue; the region in which population bursting may be based on either I_{NaP} or I_{CaN} is shown in green; the region in which

population bursting may exist without both of these currents is shown in gray; an additional region (brown) represents unstable Ca-dependent and I_{CaN} -dependent bursting (Jasinski et al. 2013, Fig. 8. Reprinted with permission)

and intrinsic properties of individual neurons. It is assumed that each spike of neuron j triggers a postsynaptic current in neuron i at time t_{kj} . This current increases the excitatory synaptic conductance in neuron i by w_{ji} , which represent the weight of synaptic connection from neuron j to neuron i . The synaptic excitation decays with synaptic constant τ_{syn} . The authors found that in a network with heterogeneous distribution of parameters (assuming normal distributions around an average value), the combination of tonic and synaptic drive determines the bursting type. The model shows that in heterogeneous populations of excitatory-connected neurons, rhythmic network bursting can depend on I_{NaP} and/or I_{CaN} or be independent of both. This finding implies that the involvement of each mechanism might depend on the neuronal excitability, the strength of synaptic interactions, and the distribution of I_{NaP} and I_{CaN} (Fig. 18).

Predictive Coding

Michael Spratling

Department of Informatics, King's College
London, London, UK

Definition

Predictive coding is both a technique for efficient information encoding and a method for performing perceptual inference. It is commonly used to model information processing in the cerebral cortex.

Detailed Description

Predictive coding models of cortical function are typically implemented as hierarchical neural networks. Such networks contain alternating populations of “error-detecting” neurons and “prediction” neurons. Figure 1 shows the connectivity between a single pair of adjacent populations in such a hierarchy, for a very simplified case where there are only two neurons in each population. The inputs come from the thalamus or are the outputs of prediction neurons at preceding stages in the hierarchy. The activity of the prediction neurons encodes hypotheses about the causes underlying the inputs to the preceding population of error-detecting neurons. The activity of the error-detecting neurons encodes the discrepancy

Predictive Coding, Fig. 1 Connectivity between adjacent pairs of neural populations in a predictive coding hierarchy

(or residual error) between the expected inputs (reconstructed from the predictions) and the actual inputs. The activations of both the prediction neurons and the error-detecting neurons are updated via an iterative process to find the combination of prediction neuron responses that best explain the inputs (in terms of minimizing the residual error) and to encode this error.

The weights from the error-detecting neurons to an individual prediction neuron determine the pattern of input activations which that particular prediction neuron represents. The strength of activation of that prediction neuron encodes the degree of belief that this specific pattern of inputs is present in the current stimulus. The full range of possible patterns that the network can represent are defined by the weights of all the prediction neurons. If these weights are represented by a matrix, W , then the rows of W (which correspond to the weights targeting individual prediction neurons) comprise “basis vectors” or “elementary components” or “codebook entries” or “atoms.” W as a whole represents a “dictionary” or “codebook” of possible representations or a model of the external world. The feedback weights, connecting the prediction neurons to the error-detecting neurons, are typically chosen to be the transpose of the feedforward weights (i.e., W^T). This means that the feedforward weight connecting a specific error-detecting neuron to a specific prediction neuron is equal to the reciprocal feedback weight connecting the same prediction neuron to the same error-detecting neuron. The feedback weights are used to reconstruct the expected inputs, based on the current prediction neuron responses. If prediction neuron responses are represented by the vector y , then this reconstruction is:

$$r = W^T y \quad (1)$$

The reconstruction thus takes the form of a linear generative model. In other words, the input is reconstructed using a linear superposition of dictionary elements where the contribution of each dictionary element is weighted by the coefficients, y .

Many other algorithms employ linear generate models and hence are closely related to predictive

coding. For example, many methods in signal processing and pattern recognition seek to approximate an input signal, x , as a linear combination of basis vectors selected from a dictionary, W^T , in proportion to a set of coefficients, y . Well-known examples include vector quantization (VQ), principal components analysis (PCA), independent components analysis (ICA), and nonnegative matrix factorization (NMF). In signal processing linear predictive coding is used to encode a temporal sequence of signals using a linear combination of signals from the recent past; hence, the dictionary is composed of previous signals and may change through time. Sparse coding (Olshausen and Field 1996) is also closely related, as it employs a linear generative model, but one in which y is constrained to contain only a few nonzero elements, so as to represent the input using a sparse set of coefficients. Unlike predictive coding these related methods are not hierarchical; however, algorithms that employ a hierarchy of generative models, and which are also therefore closely related to predictive coding, include the Helmholtz machine, the restricted ► “Boltzmann Machine,” stacked auto-encoders, and deep learning architectures in general (Arel et al. 2010).

The linear reconstruction of the inputs is compared to the actual inputs (x) in order to calculate the residual error. This calculation is performed by the error-detecting neurons and is encoded in the responses of these neurons (represented by the vector e). Two methods of calculating the error have been suggested. The more common method uses subtraction (Rao and Ballard 1999), such that

$$e = x - r \quad (2)$$

If the predictions are accurate, then the reconstructed input will equal the actual input and the error will be zero. Elements of the input vector which are not correctly predicted will result in positive or negative values in the corresponding elements of e . An alternative method uses element-wise division (Spratling 2008), such that

$$e = x/r \quad (3)$$

In this case, elements of the input that are accurately represented by the predictions will

have a value of one, and elements of the input that are not correctly predicted will result in values of e greater or less than one.

The aim of predictive coding is to find the combination of prediction neuron activations that minimize the residual error. Hence, the error-detecting neuron activations are used to calculate new prediction neuron responses with the aim of improving the predictions and subsequently reducing the error. At each iteration, the prediction neuron activations are updated as follows:

$$y \leftarrow ay + bWe \quad (4)$$

or

$$y \leftarrow y.We \quad (5)$$

where Eq. 4 is used if Eq. 2 has been used to calculate the residual errors and Eq. 5 is used if Eq. 3 has been used to calculate the residual errors. a and b are scalar parameters.

In either case, errors that are large (positive values from Eq. 2 or values greater than one from Eq. 3) correspond to elements of the input that are underrepresented in the reconstruction, and the above equation leads to an increase in the responses of prediction neurons that represent those elements of the input. Similarly, elements of the input that are overrepresented in the reconstruction, giving rise to errors that are negative (Eq. 2) or less than one (Eq. 3), reduce the responses of prediction neurons that represent those elements of the input.

While we can think of the weights, W , as defining the pattern of input activations that each prediction neuron represents, or the receptive fields (RFs) of each neuron, the prediction neurons do not behave as linear feature detectors, or linear filters, for these input patterns. If multiple prediction neurons all receive nonzero connections from the current active subset of inputs, then in the linear case each of those prediction neurons would respond in proportion to the overlap between the stimulus and that neuron's RF (i.e., $y = Wx$). In contrast, in predictive coding the activation dynamics described above cause the

prediction neurons to interact in a mutually suppressive and nonlinear manner to determine the subset of those predictions which can best explain the input pattern. This interactive process can be thought of as a form of perceptual inference in which the prediction neuron responses represent hypotheses and the inputs provide evidence in support of those hypotheses. If a prediction neuron (or subset of prediction neurons) is able to explain the input, then the evidence supporting alternative hypotheses is "explained away" (Lochmann and Deneve 2011) and the prediction neurons representing those alternative hypotheses do not respond. This perceptual inference process can also be thought of in terms for competition between the prediction neurons. Each prediction neuron effectively tries to block other prediction neurons from responding to the inputs which it represents, such that prediction neurons with overlapping RFs compete for the right to represent active inputs.

If the input remains constant, at the end of several iterations of Eqs. 1, 2, and 4 or of Eqs. 1, 3, and 5, the prediction neuron responses will typically reach a steady state where the active prediction neurons represent the linear combination of dictionary elements that can best explain the input. In the longer term, the dictionary elements (i.e., the weights W) can be adjusted to provide a better set of elementary components with which to encode the input space. Like the updating of the prediction neuron responses, this learning process is also error driven, such that

$\Delta W = fn(ye)$ if Eq. 2 has been used to calculate the residual errors

$\Delta W = fn(y(e - 1))$ if Eq. 3 has been used to calculate the residual errors.

The above description has been concerned with the interactions between pairs of error-detecting and prediction neuron populations. In a hierarchical predictive coding model, there will be multiple such pairs, and the activity in one pair will be influenced by the subsequent pair, higher up the hierarchy. For example, Eq. 4 will become $y \leftarrow ay + bWe - ce^*$ where e^* is the activation of the subsequent population of error-detecting neurons in the hierarchy and c is a scalar parameter. Alternatively, Eq. 5 will become

$y \leftarrow y.We + dW^*y^*$ where W^* and y^* are the weights and prediction neuron responses of the subsequent stage in the hierarchy and d is a scalar parameter. In either case prediction neuron responses at one stage in the hierarchy can enhance the responses of neurons representing corresponding predictions at the preceding stage.

Predictive coding is an abstract, functional model which explores the computational principles by which the cortex operates, rather than the biophysical mechanisms by which these computations may be implemented (Spatling 2011). It is therefore difficult to relate specific aspects of the model to individual components of cortical physiology. However, the most common interpretation is that cortical feedback connections carry predictions and that these act on regions at preceding stages along an information processing pathway in order to calculate the residual error which is then propagated via cortical feedforward connections (Rao and Ballard 1999; Friston 2005). Under this interpretation, pyramidal cells in the superficial layers of primary visual cortex (V1) would correspond to error-detecting neurons and some aspects of V1 complex cell behavior can be modeled by error-detecting neurons in a suitable predictive coding model (Rao and Ballard 1999). An alternative interpretation proposes that the calculation of the residual error is performed by connections intrinsic to each cortical region and hence that both cortical feedforward and feedback pathways carry predictions (Spatling 2008). Under this interpretation, pyramidal cells in the superficial layers of primary visual cortex would correspond to prediction neurons. Many properties of orientation-tuned cells in V1 can be simulated by the prediction neurons in a suitable predictive coding model (Spatling 2010, 2011).

Predictive coding has also been proposed as a model of retinal information processing (Srinivasan et al. 1982). Retinal circuitry is believed to predict the local intensity values expected at a particular spatial location (as the average intensity of all neighboring locations) and to subtract this prediction from the actual intensity. The signal generated following subtraction of the predicted information has a smaller dynamic range than the raw intensity values and

hence can be transmitted with greater accuracy using a limited range of firing rates. By removing predictable information for the transmitted data, the retina can be considered to perform redundancy reduction (the removal of statistical dependencies between neighboring pixel values) as proposed by Barlow (2001).

Definition

The axonal propagator is an operator that is applied to the initial state of a neural field variable and predicts the spatiotemporal spread of neural activity as a function of axonal distribution. It is most commonly represented as an integral operator over the axonal distribution function and the associated time delay via signal transmission. The axonal propagator is used to mathematically capture the connectivity across neuronal ensembles and derive the evolution equations of network activity.

Detailed Description

Historical Remarks

Beurle (1956) and Griffith (1963, 1965) were among the first to formulate spatially continuous evolution equations for neural fields. Wilson and Cowan (1972, 1973) and Nunez (1974) extended the neural field populations to include excitatory and inhibitory populations, refractoriness, and signal transmission delays. For specific axonal distributions, Amari (1977) obtained detailed results on pattern formation phenomena when neglecting the time delays of the axonal propagator. Jirsa and Haken (1996) generalized the expression of the axonal propagator, unified various neural field formulations, and derived its partial-differential-equation (PDE) equivalent for translationally invariant axonal distributions.

Later developments include extensions to translationally variant (Jirsa and Kelso 2000) and patchy propagators (Robinson 2006), propagators with axonal velocity distributions (Bojak and Liley 2010), and applications to large-scale brain dynamics as observed, among others, in anesthesia, gamma oscillations, epilepsy, sleep, resting state, and event-related potentials.

Mathematical Definition

Let $\psi(x, t) \in \mathbb{R}^N$ be the neural field capturing the activity of an N -dimensional neuronal population at location x and time t . The spatial domain of the neural field is denoted by Γ , which is typically a one- or two-dimensional space. The evolution in space and time of the neural field can then be described by

$$\dot{\psi}(x, t) = N(\psi(x, t)) + \int_{\Gamma} G(x, y, t - t' - \tau(x, y)) S(\psi(y, t')) dy dt'$$

where the dot designates the first time derivative, $N(\psi(x, t))$ is the local nonlinear dynamics of the neuronal population at location x , $S(\psi(y, t'))$ is the nonlinear transfer function of the neural activity generated at location y and past time point t' where $t' < t$, and $\int_{\Gamma} \int_{\Gamma} dy dt' G(x, y, t - t' - \tau(x, y))$ is the

axonal propagator. The integral kernel of the propagator factorizes into two functions, the axon distribution function $W(x, y)$ and the associated time-delayed Dirac delta function $\delta(t - t' - \tau(x, y))$, providing $G(x, y, t - t' - \tau(x, y)) = W(x, y)\delta(t - t' - \tau(x, y))$. The integral kernel G is also known as Green's function.

Equivalent Partial-Differential-Equation (PDE) Approach

Under the condition of translational invariance in physical space, $W(x, y) = W(|x - y|)$, the Volterra integral formulation of the neural field equation can be transformed into a fully equivalent PDE formulation (Jirsa and Haken 1996).

Derivation (Jirsa and Haken 1996)

With the integral kernel $W(|x - y|)\delta\left(t - t' - \frac{|x - y|}{v}\right)$ of the axonal propagator and linearization of the local dynamics around the equilibrium point, $N(\psi(x, t)) = -\frac{1}{\tau_0}\psi(x, t)$, the linear neural field equation reads

$$\dot{\psi}(x, t) = -\frac{1}{\tau_0}\psi(x, t) + \int_{\Gamma} W(|x - y|)\delta\left(t - t' - \frac{|x - y|}{v}\right) S(\psi(y, t')) dy dt' \quad (1)$$

Transforming into Fourier space, $(x, t) \rightarrow (k, \omega)$, the neural field equation reads then

$$i\omega\psi(\omega, k) = -\frac{1}{\tau_0}\psi(\omega, k) + G(\omega, k)S(\omega, k)$$

If the local dynamics is sufficiently fast as compared to the time scale characteristic for the axonal propagator, then the time derivative on the left-hand side of the equation can be adiabatically ignored. The expressions of neural field equation can be rearranged as $\psi(\omega, k) = G(\omega, k)S(\omega, k)$ where we set $\tau_0 = 1$ for simplicity. Splitting $G(\omega, k)$ into numerator and denominator, $G(\omega, k) = \frac{P(\omega, k)}{Q(\omega, k)}$, we obtain $Q(\omega, k)\psi(\omega, k) = P(\omega, k)S(\omega, k)$.

The expressions $Q(\omega, k)$ and $P(\omega, k)$ are completely determined by the axonal propagator, in particular the properties of the axonal and delay distributions. We perform another Fourier transformation back into physical space-time and make the following identifications: $(ik, i\omega) \rightarrow \left(\frac{\partial}{\partial x}, -\frac{\partial}{\partial t}\right)$ where the latter denote the partial derivatives with respect to space and time, respectively. Then, the above neural field equation can be expressed through the equivalent PDE formulation

$$\sum_{i,j} q_{ij} \frac{\partial^i}{\partial t^i} \frac{\partial^j}{\partial x^j} \psi(x, t) = \sum_{i,j} p_{ij} \frac{\partial^i}{\partial t^i} \frac{\partial^j}{\partial x^j} S(\psi(x, t)) \quad (2)$$

where q_{ij}, p_{ij} are constant coefficients.

Special Cases in 1D and 2D with Exponential Distributions

For the special 1D case of exponential distribution of axonal fiber length, $W(|x - y|) = \frac{1}{2\sigma} \exp(-|x - y|/\sigma)$, where $x, y \in \mathbb{R}$, the corresponding PDE is the Jirsa-Haken equation:

$$\left(\frac{\partial^2}{\partial t^2} + 2\omega_0 \frac{\partial}{\partial t} + \left(1 - v^2 \frac{\partial^2}{\partial x^2} \right) \right) \psi(x, t) = \omega_0 \left(\omega_0 + \frac{\partial}{\partial t} \right) S(\psi(x, t))$$

with $\omega_0 = \frac{v}{\sigma}$.

For the special 2D case of exponential distribution of axonal fiber length, $W(|x - y|) = \frac{1}{2\pi\sigma^2} \exp(-|x - y|/\sigma)$, where $x, y \in \mathbb{R}^2$, the corresponding PDE reads

$$\left(\frac{\partial^2}{\partial t^2} + 2\omega_0 \frac{\partial}{\partial t} + \left(1 - v^2 \frac{\partial^2}{\partial x^2} \right) \right)^{3/2} \psi(x, t) = \omega_0^2 \left(\omega_0 + \frac{\partial}{\partial t} \right) S(\psi(x, t))$$

with $\omega_0 = \frac{v}{\sigma}$.

Expansions

Axonal and velocity distributions shape Green's function of the axonal propagator and have been addressed for various configurations. For short fiber lengths the integral kernel in (1) can be expanded into a Taylor series and truncated for higher orders (Jirsa 2009), which is equivalent to a truncation of the order of differentials in (2). Equivalently, in Fourier space, the expressions of the neural field equation and the axonal propagator can be rearranged as $G(\omega, k) - {}^1\psi(\omega, k) = S(\omega, k)$ and expanded via a slow-wave approximation giving the same results (Jirsa 2009). Distributions of short-range excitatory and longer-range inhibitory fibers result in a Mexican hat distribution function of the axonal propagator, which then causes the following PDE:

$$\frac{\partial}{\partial t} \psi(x, t) = N(\psi(x, t)) + D_1 \frac{\partial^2}{\partial x^2} \psi(x, t) - D_2 \left(\frac{\partial^2}{\partial x^2} \right)^2 \psi(x, t)$$

resembling essential features of pattern formation dynamics as known from the Swift-Hohenberg equation. The latter is known to give rise to self-sustained spatial patterns thought to be involved in working memory. Other modifications of the axonal propagator include periodic modulations of the integral kernel mimicking connectivity properties such as are seen in the visual cortex (Robinson 2006), enabling the generation of features including orientation preference and wave number selectivity. Bojak and Liley (2010) extended the axonal propagator to include axonal velocity distributions and suggested that longer fibers tend to have higher transmission speeds.

Applications

Initial applications focused on the approximation of symmetric axonal distributions, resulting in translationally invariant axonal propagators. Jirsa and Haken (1996, 1997) discussed sensorimotor coordination phenomena in their original work. Using a modified Bessel function of 2nd kind in the propagator, Robinson et al. (1997) derived the Jirsa-Haken equation and added a corticothalamic circuit with time delay to explain spectral features of spontaneous activity. Later work expanded these results in much detail (Breakspear et al. 2003; Freyer et al. 2011; Wright and Liley 1995, 1996, Liley et al. 1999; Robinson et al. 2001b), as well as other applications including evoked potentials (Robinson et al. 2001a), anesthesia (Bojak and Liley 2005; Hutt 2013), and epilepsy (Breakspear et al. 2006). Independent of any neurobiological motivation, researchers have also explored the pattern-forming capacities of neural fields for artificially designed axonal propagators to study generic principles of spatiotemporal pattern formation and computation (Laing 2005). It was noted early on that the translationally invariant symmetry imposed on the axonal propagator will constrain the possible range of dynamic solutions (Jirsa et al. 2002) and further extensions will be needed accommodating the translational variance of the axonal propagator, $G(x, y, t - t' - \tau(x, y)) \neq G(|x - y|, t - t' - \tau(x, y))$. Such extensions are nowadays at the core of

connectome-based modeling efforts (see Deco et al. (2011, 2013) for reviews) and are integrated in modern neuroinformatics efforts as pioneered by Bojak et al. (2010, 2011) and The Virtual Brain (Sanz Leon et al. 2013).

information about the limb's actual position (Sober and Sabes 2003). Any discrepancy between the two signals can be used to adjust the motor command to correct the course of the limb trajectory. The importance of proprioception in movement is especially apparent in patients with impaired proprioception; these patients tend to display highly uncoordinated movements despite having an intact motor system. The movements of these patients are slow, jerky, and usually inaccurate (Sacks 1985). If the proprioceptive impairment is temporary and the sense is able to be restored, movements become normal again.

Proprioceptors

There are several types of proprioceptive receptors (Fig. 1), located in the muscles, in the skin, and in the joint capsules. Muscle proprioceptors, which are thought to be the primary contributors to proprioception, come in two types: muscle

Proprioception

Chicago, Chicago, IL, USA

Definition

Proprioception is the awareness of the position and movements of one's body.

Detailed Description

Proprioception refers to the sense of one's body, in particular, the position of body parts relative to each other, as well as their movements through space. Proprioception plays an important role in the planning and execution of actions. Indeed, during goal-directed motor behavior, the estimation of the limb's position derived from the signals in motor cortex is compared with proprioceptive

Proprioception, Fig. 1 Proprioceptors can be found in the muscles (*left*), in the skin (*top*), or in the joint capsules (*bottom*)

spindles and Golgi tendon organs. Muscle spindles convey information about the rate of change in a muscle's length. They are innervated by gamma motor neurons which, upon activation, can modify the sensitivity of the muscle spindles. Golgi tendon organs signal muscle force generated by muscle contraction. The information signaled from muscle proprioceptors can be integrated to determine the position of the limbs (Goodwin et al. 1972; McCloskey et al. 1983).

One population of receptors in the skin is sensitive to skin stretch and has been implicated in proprioception (Wheeler et al. 2010). Indeed, when we flex a joint – say, the elbow – the skin on the outer aspect of the joint becomes tauter and stretch receptors that innervate that skin become activated. Conversely, when we extend that joint, those stretch receptors become less activated. Signals from these stretch receptors can then be used to infer joint position and movements. Another type of proprioceptor, the joint capsule receptor, signals joint positions during movement or static postures. However, these receptors typically fire

only at the extreme ends of the joint's range and may only be involved in providing a signal geared toward preventing overextension of the joint (Clark and Burgess 1989). Signals originating from either skin or joint capsule proprioceptors probably play a secondary role to that of muscle proprioceptors, as when the former are removed, proprioception is only slightly degraded (Edin and Johansson 1995; Goodwin et al. 1972).

Pathway

Information about the limb's position and movements is signaled from the proprioceptors and is carried to the brain by long, pseudo-unipolar afferents. These afferents relay the signals into and up the ipsilateral dorsal column of the spinal cord. These axons synapse onto the dorsal column nuclei in the brainstem. Projections from these nuclei cross the midline at the medulla oblongata and synapse onto the contralateral ventral posterior lateral nucleus of the thalamus. From the

Proprioception, Fig. 2 Primary somatosensory cortex (S1) and the cerebellum receive proprioceptive signals

thalamus, the signals are then projected to cortex. Proprioceptive signals are also used to maintain postural stability during sitting, standing, simple gait tasks, or other movements or postures that do not require volitional control (Johnson et al. 2008). These signals also travel up the dorsal column of the spinal cord through the brainstem but terminate in the ipsilateral cerebellum.

Proprioception in the Brain

Proprioceptive neurons in the thalamus project to areas 3a and 2 in primary somatosensory cortex (S1) (Fig. 2). Area 3a is located in the rostral bank and fundus of the central sulcus and borders both primary motor cortex (area 4) and area 3b, an area in S1 which receives primarily cutaneous input. Area 3a is implicated in sensorimotor integration given its proximity to and its dense reciprocal connections with motor cortex. In contrast, area 2 is located in the caudal region of the postcentral gyrus and receives both proprioceptive and cutaneous input, the latter most likely via projections from areas 3b and 1, two primarily cutaneous areas. Area 2 is thought to play a role in combining both cutaneous and proprioceptive inputs to achieve a three-dimensional percept of the position of the limbs and what those limbs are contacting. The cerebellum mediates aspects of proprioception required for the coordination and timing of movement.

Proprioceptive Feedback to Central Pattern Generators

► Sensory Input to Central Pattern Generators

Proprioceptor Models

Arthur Prochazka

Centre for Neuroscience, School of Molecular and Systems Medicine, University of Alberta, Edmonton, AB, Canada

Definition

Charles Sherrington coined the term “proprioception” to describe the sensing of the body’s own movements (Sherrington 1907). He included receptors of the vestibular apparatus as well as receptors in deep tissues such as muscles in his definition. Proprioceptive signals are an important component of feedback to the CNS for the control of posture and movement. Input to the spinal cord from proprioceptors influences the activity of muscles via reflex connections to motoneurons. It is also conveyed to structures in the brainstem, midbrain, cerebrum, and cerebellum involved in motor control. Neuromechanical models

incorporating proprioceptive feedback have become increasingly influential in the understanding of the neural control of movement.

Detailed Description

In 1834, Charles Bell proposed that mammalian muscles contain sensory receptors that mediated both a “muscle sense” underlying the subconscious control of movement (Bell 1834) and the conscious sensation of position and movement of limbs, later termed “kinesthesia” (Bastian 1888). Bastian argued that not only muscle receptors but also cutaneous receptors contribute to kinesthesia (Bastian 1888).

Proprioception in Invertebrates

Several important aspects of our understanding of motor control have come from studies of invertebrates. Invertebrates have sensory receptors that in some cases bear an uncanny resemblance to mammalian proprioceptors. For example, crustacean thoracicocoxal muscle receptor organs have two types of sensory afferents, as do mammalian muscle spindles (Bush 1981). Furthermore, their sensitivity is controlled by two types of efferent motoneurons, similar to the fusimotor neurons that control the sensitivity of mammalian muscle spindle afferents. Neuromechanical models of sensory inputs and muscle responses in invertebrates have been reviewed elsewhere (Pearson et al. 2006; Zill et al. 2012). This entry will focus on models of proprioception in mammals.

Properties of Mammalian Proprioceptors

In mammals, proprioception is mediated by muscle spindles (Hulliger 1984), Golgi tendon organs (Proske and Gregory 2002), joint receptors (Johansson et al. 1991), and skin receptors (Zehr and Stein 1999). The human upper extremity contains about 4000 muscle spindles, 2500 Golgi tendon organs, and a few hundred joint receptors

(Barker et al. 1962; Hulliger 1984; Voss 1971). Cutaneous receptors far outnumber those in muscles, tendons, and joints: the human hand alone has around 17,000 myelinated cutaneous afferents (Johansson and Vallbo 1979). However, only a small proportion of these respond to skin stretch around joints, thus providing proprioceptive information.

Muscle Spindles

Nearly all mammalian muscles contain fusiform receptors called muscle spindles (Hulliger 1984; Prochazka 1996). The average number of spindles in a muscle is roughly $38 \times (\text{cube root of mass in grams})$ (Banks and Stacey 1988; Hulliger et al. 1985; Prochazka 1996). Thus, a 64 g muscle contains about 152 spindles. A typical muscle spindle is 0.5–10 mm long and consists of 6–10 “intrafusal” muscle fibers attached at each end to the surrounding “extrafusal” muscle fibers. Intrafusal muscle fibers do not contribute significantly to the force developed by the muscle’s extrafusal fibers. Their only role is to control the stretch sensitivity and offset firing rate (“bias”) of the spindle’s sensory afferents.

The muscle spindle has a central noncontractile sensory region innervated by one or two group Ia afferent axons, each terminating in a primary sensory ending and up to five group II afferents terminating in secondary sensory endings. Each spindle is also innervated by 10–12 γ -fusimotor axons and often by a β -skeletofusimotor axon, which also innervates extrafusal muscle fibers.

In the absence of fusimotor activity, group Ia and II afferents respond to changes in muscle length and velocity. There is a continuum from the smallest diameter group II afferents with low velocity sensitivity to the largest diameter Ia afferents with high velocity sensitivity. Group Ia and II afferents both have nonlinear aspects of response, e.g., sensitivity to small-amplitude length changes that is much larger than that to large-amplitude length changes, a power-law dependence of Ia firing on velocity, stretch sensitivity that depends on mean muscle length, history-dependent initial burst responses, a decline in velocity-sensitive response during shortening that is greater than the increase during lengthening, creep (a slow

decline in firing after a stretch during γ_d action), and competition (occlusion) between effects on Ia firing of different γ efferents (Hulliger 1984; Prochazka 1996). These nonlinearities pose problems for modeling.

Most mammalian muscle spindles contain three types of intrafusal muscle fiber: a dynamic bag₁ (DB1 or b₁), a static bag₂ (SB2 or b₂), and 2–11 chain (c) fibers. The dynamic b₁ fiber is selectively activated by dynamic fusimotor (γ_d) or β_d skeletofusimotor axons, though b₂ and chain fibers may sometimes be co-activated (Emonet-Denand et al. 1977). The b₂ and chain fibers are activated by static fusimotor (γ_s) or skeletofusimotor (β_s) axons. More details of intrafusal and fusimotor subdivisions in different species are available elsewhere (Matthews 2011).

By contracting and stiffening b₁ intrafusal muscle fibers, γ_d action imparts more stretch to the sensory region, increasing Ia afferent stretch sensitivity (“gain”) up to fivefold, except when muscle displacements are so small that some intrafusal cross-bridges remain attached. γ_d action also causes a small increase in Ia offset firing (bias) (Emonet-Denand et al. 1977). The phase of responses to sinusoidal stretching is little changed, i.e., gain is increased in the absence of a change in phase, which is important from a modeling point of view. Strong γ_s action adds a large bias to both Ia and II afferent firing rates, attenuates Ia stretch sensitivity by up to 50 %, but increases group II afferent gain up to twofold. Paradoxically, weak γ_s action can *increase* rather than decrease Ia gain (Hulliger et al. 1985). The terms dynamic and static fusimotor action are in fact misleading, in that both types alter mainly the gain and offset rather than the dynamics of group Ia and II responses to stretch. An interactive animation of some of these interactions is available online (Kowalczewski and Prochazka 2006).

There is still considerable disagreement on the way the CNS uses γ -motoneurons to control the offset and gain of muscle spindles during voluntary movement, which is a major problem for modelers. This will be discussed again below.

Golgi Tendon Organs (GTOs)

These are encapsulated structures 0.2–1 mm long, usually located at musculotendinous junctions (Barker 1974). There are about 80% as many GTOs in a typical limb muscle as spindles. Their sensory endings, which become group Ib afferent axons, are entwined among the tendinous strands of 10–20 motor units, a given motor unit affecting 1–6 tendon organs (Jami 1992; Proske 1981). Unlike spindles, GTOs do not have a mechanism akin to fusimotor action to modulate their sensitivity. Ib afferents can have a high threshold to stretch of the inactive muscle but respond sensitively to force actively generated by the motor units with which they are associated (Houk and Henneman 1967; Stephens et al. 1975).

Though individual tendon organ afferents signal increasing muscle force with steps in firing rate corresponding to the progressive recruitment of motor units, when the firing of several Ib afferents is summed, the net ensemble firing rate is monotonically related to whole muscle force (Prochazka and Gorassini 1998a).

Recently, it was shown that the inclusion of signals from Ib afferents along with those from spindle afferents improved the discrimination of different muscle stretches (Bergenheim et al. 1996). In a study of human grasp (Dimitriou and Edin 2008), the decoding of velocity by muscle spindle afferents was improved by including the firing rates of tendon organ afferents. Because tendons lengthen during muscle contraction, muscle spindles “see” a distorted version of muscle length changes, so tendon organ information could be used to correct for this in proprioception (Kistemaker et al. 2013).

Cutaneous Receptors

Slowly adapting type II and III cutaneous receptors located over or near limb joints respond to the stretching of skin during movement, their firing rates correlating well with a weighted sum of joint angle and joint angular velocity (Aimonetti et al. 2007; Clark et al. 1979; Edin 2001; Edin and Johansson 1995). In fact their signals may be more closely related to joint rotations than those of muscle spindle afferents, which as we have seen above are affected by tendon strain and

fusimotor efferent activity, which varies during active movement in ways that are not fully understood (Aimonetti et al. 2012). Stimulating cutaneous afferents can produce movement illusions (Collins and Prochazka 1996; Edin and Johansson 1995), and anesthetizing them reduces kinesthetic acuity (Lowrey et al. 2010), suggesting an important role in proprioception and kinesthesia.

Joint Receptors

Stretch receptors in joint capsules were initially assumed to signal joint rotation over the full range of motion (Boyd and Roberts 1953) until two research groups reported that most joint receptors were unresponsive in the midrange (Burgess and Clark 1969; Tracey 1979). Subsequent work indicated that at least some joint receptors do signal over the full range of motion (Carli et al. 1979; Ferrell 1980; Ferrell et al. 1987; Godwin-Austen 1969; Lund and Matthews 1981; Zalkind 1971), though some of these may have been muscle spindles or tendon organs in nearby muscles (Clark et al. 1985; Gregory et al. 1989; McIntyre et al. 1978). Loading of the joint capsule may be necessary to sensitize joint receptors enough to confer midrange responsiveness on them (Grigg and Greenspan 1977). Most joint afferents have group II conduction velocities (Burgess and Clark 1969), and their reflex connections with α -motoneurons are polysynaptic and relatively weak (Johansson et al. 1991). They may have a special role in inhibiting muscles when joints are damaged (Iles et al. 1990).

Models of Proprioceptors

Muscle Spindle Models

Numerous muscle spindle models have appeared in the literature (summarized in Table 1). It has been claimed that these models fall into one of two categories: early “black box” models comprising input–output functions fitted to experimentally obtained Ia or II afferent responses to length changes and later “structural models” based on the mechanical interaction between the sensory transducer component of the spindle and the intrafusal muscle component (Lin and Crago

2002b; Mileusnic et al. 2006; Schaafsma et al. 1991). This is a little unfair, as sensory transducer properties and the role of intrafusal mechanics were in fact taken into account in the development of even the earliest spindle models (Chen and Poppele 1978; Crowe 1968). The progression of modeling should rather be described as a series of refinements in which fusimotor action and various nonlinearities associated with different components of the spindle were progressively included, resulting in better fits to experimental data but also in an increase in the number of free parameters.

The first spindle models were linear transfer functions developed to fit the passive responses of Ia afferents to triangular and sinusoidal length changes and to sudden increments and decrements in fusimotor stimulation (Andersson et al. 1968; Crowe 1968; Lennerstrand 1968). Ia firing rate was modeled adding length and velocity terms. The Andersson model added a second length term, the gain of which depended on velocity (Table 1 top row). Andersson’s fusimotor response model (not shown in Table 1) comprised a single-pole low-pass filter and an impulse generator. Matthews and Stein published a simplified version of these models, a single-zero high-pass filter with a turning point of 1.5 Hz (Matthews and Stein 1969). Further refinements of the transfer function models were introduced by Poppele’s group, with the addition of poles and zeroes that took into account slower adaptive components of Ia afferent response (Chen and Poppele 1978; Poppele and Bowman 1970; Table 1). Interestingly, whereas an additional term, $(s + 4)$, was required to fit the small-amplitude Ia model to large-amplitude data (Table 1), the linear transfer function developed for group II afferents fitted the empirical data for both small and large amplitudes of stretch (Poppele and Bowman 1970). A slightly different Ia model was published by Terzuolo’s group (Chen and Poppele 1978; Rosenthal et al. 1970). The fits of these Ia models to empirical frequency response data were not compared head-to-head, but their Bode plots are quite similar.

The nonlinearities mentioned above were discussed by all of these authors, particularly the dependence of Ia stretch sensitivity on muscle

Mileusnic et al. (2006)	Complex model not completely specified in the reference	N/A	Partial occlusion between γ_s and γ_d action included	Power-law relationship of Ia rate and velocity. Tendon strain during active movement included

velocity, the high stretch sensitivity to very small muscle length changes (<2% muscle strain), and the initial burst response at the onset of large ramp stretches. These latter two behaviors are related and have been attributed to the formation of stable cross-bridges in resting intrafusal muscle fibers that are then ruptured when muscle strain exceeds 2% (Morgan et al. 1984). They are not present in cyclical movements or during fusimotor drive, and yet much attention was paid to them in some of the later, more complex models.

In a study in which six of the simpler models were compared (Prochazka and Gorassini 1998b), the linear transfer function models performed reasonably well when tested on simulated Ia responses to slow ramp-and-hold stretches like those used by Lennerstrand et al. However,

when tested on Ia firing rates recorded in normal locomotor movements, the r^2 values obtained with the Matthews and Stein model were in the range 0.41–0.58, which was well below the range 0.83–0.94 achieved by the more recent models tested.

One of the reasons the later models performed better was that some of them incorporated a power-law relationship between muscle velocity and Ia firing rate (the peak muscle velocities in the locomotor data were much higher than those in the acute experiments upon which linear models had been based). A nonlinear Ia response to stretch velocity had been noted in the late 1960s (Matthews 1963), and a power-law relationship was proposed in the early 1970s (Schafer 1973), but it was not until the work of Houk and

colleagues a decade later that it became generally accepted. Schafer and colleagues reported a mean value of 0.56 of the exponent in their power-law function (see Table 1), and this produced better fits to the data in awake animals (Prochazka and Gorassini 1998b) than the value 0.3 proposed later (Houk et al. 1981). A simple way of thinking of Schafer's relationship is that the Ia response to length changes is approximately proportional to the square root of muscle velocity. The Schafer model does not include an offset term, and this omission was remedied by Houk and colleagues (Hasan 1983; Houk et al. 1981), who also proposed a scaling of the velocity response by muscle length.

Hasan's model, based on biomechanical considerations, incorporated nonlinear elements, including a velocity^{0.3} term. The main new feature here was a term that modeled the initial burst response of Ia afferents to ramp stretches, but as pointed out above, this behavior only occurs in muscle stretches that start from rest and is inappropriate for rhythmical movements. The Houk and Hasan Ia models performed well in the tests on the normal locomotor data but only after the velocity exponent was changed from 0.3 to 0.6 (Schafer 1973), after the models were adjusted to cope with negative velocities (i.e., muscle shortening), and after parameter values had been selected by trial and error, in particular to reduce the initial burst component. The modified Hasan model overemphasized the fall in Ia firing rate when muscle velocity changed from positive to negative, a situation for which the original model had admittedly not been developed. Fusimotor action was not explicitly included in either of these models, though it was pointed out that this could be done by altering parameters.

The next development was a neuromechanically based model that included separate inputs to intrafusal muscles from static and dynamic fusimotor neurons (Schaafsma et al. 1991). It also included a stiction component that produced initial burst responses. An all-or-nothing competition between the two fusimotor inputs during lengthening and shortening (complete occlusion) was assumed. The model

had over 20 parameters, which, when adjusted appropriately, resulted in reasonable fits to data from acute experiments, but in the absence of tests on data from normal movements or quantitative comparisons with other models, it is difficult to judge the relative merits of this model. Implementing it with commercially available software was found to be a challenge (Maltenfort and Burke 2003).

As mentioned, some of the above models were compared in a study of afferent recordings obtained during voluntary locomotion in normal cats (Prochazka and Gorassini 1998b). The best fits were obtained with a fairly simple nonlinear model based on those of Schafer, Houk, and Hasan (Table 1; Fig. 1). This model assumed a constant level of γ_d action and a modest amount of γ_s action linked to muscle activation (represented by the rectified, smoothed electromyographic activity of the receptor-bearing muscle). Though this model may be adequate for neuromechanical models of locomotion, it may not generalize to other types of movement in which γ_d and γ_s activity may be elevated or vary phasically over a large range.

In 2002, a very detailed neuromechanical model of the muscle spindle was developed (Lin and Crago 2002b). This model took into account all of the nonlinearities mentioned above and ran in the widely used MATLAB/Simulink software environment. In defense of the complexity of the model and its large number of parameters (89), the authors argued that compared to previous simpler models, it was likely to be more accurate under a wide range of conditions, it could more easily be modified as knowledge was gained, and since the parameters did not vary with operating conditions, parameter estimates could be drawn from a wider pool of data rather than from one organism. The model was incorporated along with a Golgi tendon organ model into an analysis of the stretch reflex. Several features of empirically observed stretch reflexes were accurately simulated, including linearization effects and the dependence on operating force and initial muscle length. The model did not accurately predict the reflex responses at higher stretch velocities, evidently

Proprioceptor Models, Fig. 1 Comparison of the predictions of six models of muscle spindle Ia afferent responses. The target Ia firing rate (black trace repeated in panels A–F) was computed from individual firing rates of an ensemble of nine hamstrings Ia afferents recorded during locomotion in the normal cat. Top to bottom: Mean

muscle activity (EMG), muscle origin-to-insertion length, fitted firing profiles A–F: red lines superimposed on the target ensemble data. Right column: linear regressions of the target firing rate versus the firing rate predicted from the length signal by each model (From Prochazka and Gorassini (1998b))

due to failure of the extrafusal muscle model. Interestingly, underdamped “ringing” responses occurred in the simulated Ia, II, and Ib afferents and α -motoneurons, which might have resulted from exaggerated initial bursts, or too high a reflex loop gain.

In 2003, Maltenfort and Burke (2003) added explicit fusimotor action to the early transfer function models (Andersson et al. 1968; Crowe 1968; Lennerstrand 1968). A power-law relationship related firing rate to muscle velocity. The main aim of the study was to explore the positive feedback effect of β skeletofusimotor in stretch reflexes. In reflex simulations, it was found that β skeletofusimotor action produced significant increments in Ia afferent firing. This could either amplify existing γ drive or compensate for insufficient γ bias for the task at hand. The Maltenfort and Burke model has not been compared quantitatively with other models. It does have the advantage of relative simplicity. The omission of stiction effects in this model may paradoxically make it more suitable than some of its more complex competitors for modeling the neuromechanical control of movement.

The most recent model (Mileusnic et al. 2006) incorporates all of the known nonlinearities and also takes into account the fact that muscle spindles do not “see” all of the changes in muscle length that occur during voluntary movement, because stretching of the tendons in series with muscle accounts for some part of the changes in muscle length. The model has over 20 parameters, and because some of the equations did not have analytical solutions, stepwise simulations were performed in a MATLAB/Simulink environment. One of the strengths of this work is that the model was tested not only on data obtained in acute experiments but also on recordings from afferents and γ -motoneurons obtained in decerebrate cats walking on a treadmill (Taylor et al. 2000). With the appropriate handcrafting of parameters, the decerebrate data were well fitted. The very large fluctuations in γ activity that seem to characterize decerebrate locomotion provided a good test bed for the simulations. An interesting result in this study was that a velocity exponent of 0.3, as

suggested by Houk et al. (1981), gave better fits than the 0.5–0.6 values in other studies (Prochazka and Gorassini 1998b; Schafer 1973). It was pointed out by Mileusnic et al. that their model could in principle allow γ activity occurring in normal behaviors to be deduced from recordings from spindle group II afferents and, with some caveats, from spindle Ia afferents as well.

Golgi Tendon Organ Models

Few individual Ib afferents fire at a zero force level (Houk et al. 1971). Their firing rate jumps when a force threshold is reached, this threshold varying widely between Ib afferents in the same muscle. Individual Ib afferents are more sensitive to changes in muscle force when motor units with muscle fibers inserting into their receptor capsule are active (Jansen and Rudjord 1964). This results in steplike increases in firing rate with the progressive recruitment of each associated motor unit. When two motor units engaging a Ib afferent are stimulated together, the net rate of discharge is less than the sum of individual responses (Gregory et al. 1985). In acute experiments in which motor units were electrically activated, individual Ib firing rates saturated at high force levels, but when motor units were recruited physiologically during reflex contractions, the relationship between individual Ib firing rate and muscle force was remarkably linear (Crago et al. 1982).

As in the case of muscle spindle afferents, ensemble responses smooth out some of the nonlinear responses of individual Ib afferents. In the Crago et al. study, the firing rates of 19 individual Ib afferents were summed. The combined firing rate had a near-zero force threshold, and recruitment steps were absent. On the other hand, the aggregated firing rate saturated at high force levels even though most of the contributing Ib afferents had responded linearly. This is because more of the afferents were recruited at lower forces than at higher forces, and so their onset firing rates summed more at the lower end of the force range. This resulted in a logarithmic relationship between ensemble Ib firing rate and force (Lin and Crago 2002a; Table 2), though a recent model

suggested a power-law relationship (Mileusnic and Loeb 2009, Fig. 9).

Regarding the dynamics of Ib responses to time-varying forces, several transfer functions have been proposed (Table 2; Anderson 1974; Houk and Simon 1967; Roberts et al. 1971). These transfer functions all provided good fits to empirical data, though no quantitative comparisons were published. A slightly modified version of the Anderson transfer function gave a good fit to the firing profile of a Ib afferent recorded during imposed stretches in a conscious cat, in which the force applied had been monitored (Appenteng and Prochazka 1984). In another study, muscle force was reconstructed from the ensemble Ib firing rate recorded during voluntary locomotion, by using the inverse of the Houk and Simon model (Prochazka 1999). Interestingly, the form of the Ib transfer functions is similar to that of the transfer functions developed for muscle spindle group Ia and II endings (Poppele and Bowman 1970). This indicates that the transduction process in GTO receptor endings is similar to that in receptor endings in the muscle spindle, in spite of their very different morphology. Another similarity with spindle II afferents is that Ib afferents tend to fire fairly regularly, except at low levels of active force, when unfused twitch contractions of newly recruited motor units summate and “beat,” causing characteristic bursts of Ib firing (Jami 1992). In a recent model of the stretch

reflex, two of the terms in the Houk and Simon model were discarded, and the logarithmic non-linearity mentioned above was added (Lin and Crago 2002a; Table 2). This model of ensemble Ib firing is the most current and probably the most useful in relation to neuromechanical modeling of reflex and voluntary movement.

Modelers more interested in the specifics of the firing of individual Ib afferents are referred to a recent mechanical model that takes into account the types of motor units acting on a GTO, the order of their recruitment, adaptation of the sensory endings to the time course, and combination of motor unit inputs, occlusion between transduction regions, and other nonlinearities mentioned above (Mileusnic and Loeb 2006, 2009).

Cutaneous Receptor Models

The cutaneous receptors best suited to signal joint angle are slowly adapting type II receptors (SAII) which respond to stretching of the skin, in some cases several centimeters from the point of maximal skin strain (Edin 2001, 2004; Horch et al. 1977). Slowly adapting type I receptors (SAI) respond more locally, fire less regularly, and adapt more rapidly. Finally, there are at least four kinds of hair follicle and glabrous skin receptors which respond to dynamic components of hair deflection or skin stretch (Willis and Coggeshall 1991). Skin stress and strain over and near moving joints is directional, and the location and

orientation of cutaneous receptors determine their “preferred direction of firing,” i.e., the direction of skin strain and joint movement to which they respond best (Aimonetti et al. 2007; Edin 1992).

Mechanical analysis suggested that SA receptor firing recorded during skin indentation in monkeys was correlated with skin strain (Phillips and Johnson 1981). However, *in vitro* studies of patches of innervated rat skin indicated that SAI afferents respond to stress, rather than strain, at least under circumstances in which these variables were independent (Grigg and Del Prete 2002). During phasic joint movements, it seems reasonable to assume a covariation of stress and strain. Viscoelastic behavior such as “creep” could make these variables diverge in maintained positions of a limb.

In human studies in which recordings were obtained from cutaneous afferents with the use of percutaneous needle electrodes, SA afferents responded to skin indentation in a nonlinear manner, the static response being best fitted by a power function (Knibestol 1975). In a later human neurography study, ramp-and-hold stretching of the skin was imposed by a displacement servo with caliper-like prongs (Edin 1992, 2004). This provided a more direct measure of strain. A detailed quantitative analysis of the static and dynamic responses of the cutaneous afferents was performed. Slowly adapting type II afferents (SAII) and to some extent SAIII afferents responded both rapidly and consistently at low strain velocities; at higher velocities, SAI and fast-adapting FAI afferents were recruited at longer latencies. Good fits were obtained for both SA and FA afferents when their responses were modeled by a simple power function of velocity ($r^2 > 0.9$ for 95 % of the units) (Table 2). The exponent of the power function varied between afferents but was generally less than 1, which is reminiscent of the Schafer and Houk models of muscle spindle afferents.

In an analysis of the firing rates of SA cutaneous receptors of the human knee, good fits were obtained with a linear combination of joint angle and joint angle velocity (Edin 2001; Table 2; Fig. 2). However, a previous study had shown a nonlinear relationship with joint angle, possibly

also following a power law (Edin 1992; Fig. 2), and a later study showed a power-law relationship with angular velocity (Edin 2004). The equation in the last row of Table 1 is proposed here, to take these nonlinearities into account. Regarding the gain and offset terms, these are provided in the original publications. It was pointed out that the larger the joint, the larger the skin strain, and therefore presumably the larger the sensitivity of cutaneous receptors to joint rotation (Edin and Johansson 1995).

Joint Receptor Models

As discussed above, there is no consensus on the response properties of joint receptors, some researchers claiming that they are incapable of signaling joint rotation except at the extremes and others disputing this. Under these circumstances, the only useful data relevant to modeling is the fact that joint receptors are slowly adapting and have response properties similar to SA cutaneous receptors. One approach that could be taken would be to assume that their contribution to proprioception would be similar to that of SA cutaneous receptors (Williams 1981).

General Comments: Which Models to Choose?

In the simpler spindle models, fusimotor action mediated via intrafusal muscles is represented by just one or two parameters: gain and offset, the assumption being that these are the two main effects of fusimotion on spindle afferent responses. The later models have parameters representing up to three types of fusimotor action, but because there is conflicting evidence on the way in which the CNS controls fusimotor neurons in normal movements, it is unclear whether these additional parameters lead to better predictions of afferent firing in awake animals and humans.

Unfortunately, so far, the performance of different muscle spindle models has only been compared head-to-head in a single study, and this was restricted to some of the simpler models (Prochazka and Gorassini 1998b). Consequently, the only quantitative criterion upon which the

Proprioceptor Models, Fig. 2 Knee joint movements and associated firing rate of four SA III cutaneous afferents (a–d) recorded by neurography during voluntary knee flexion and extension. Schematic shows location of the receptors. The instantaneous discharge rates of the

receptors were fitted by a model comprising a linear combination of knee angle and angular velocity (dotted lines superimposed on the recorded discharge rate) (From Edin (2001))

more complex models can be compared with each other and with the simpler models is the reported variance accounted for (r^2) in fitting the available

data on afferent responses to length changes and fusimotor stimulation. Qualitative evaluation of specific features of response can be useful, e.g.,

the initial burst in Ia afferents at the onset of stretch or occlusion of fusimotor action in ascending and descending phases of a stretch. In light of the complexities, the reported r^2 values of fits to experimental data for most of the models have been surprisingly good, generally exceeding 0.8 and in some cases 0.9.

This raises the question of the intended purpose of the model. Complex structural models are well suited to modeling fusimotor action and non-linear responses and to describing the contributions of the different internal elements of individual receptors. However, if the focus is more on the ensemble afferent input to the CNS, features such as initial bursts can be misleading, because they tend to occur asynchronously in different afferents. CNS neurons that receive synaptic inputs from first-order afferents integrate the inputs from many receptors. This “washes out” asynchronous responses of individual receptors. Simpler models that do not attempt to replicate such transients may therefore paradoxically be more suitable for such applications, and of course they have the added advantage of simplicity. Another major issue is the lack of consensus in the literature regarding the way in which fusimotor activity is modulated in conscious animals and humans. If the activity of both types of fusimotor neurons remains fairly constant for movements of a given type or if there is a predictable relationship between their activity and another variable such as α -motoneuronal activity (which can be measured with electromyography), the net fusimotor effect can be modeled to some extent by adjusting the gain and bias terms of the simpler models and, in theory, more accurately by adjusting parameters in the complex models. If fusimotor activity is highly modulated, detailed parameter adjustments may succeed in the more complex models (e.g., as shown in Mileusnic et al. (2006)) but only if the individual time courses of γ_d and γ_s activity are known.

Regarding the accuracy that is actually required of a model, again this depends on the task at hand. For example, the gain of displacement and force feedback in spinal stretch reflexes is probably quite low. Open-loop gains of spindle

feedback of more than 1 or 2 tend to cause instability because of the sluggish responses of load-moving muscles (Prochazka et al. 1997a, b). Because of the low gain, such reflexes probably contribute quite modestly to load compensation (Prochazka et al. 2002), and therefore, r^2 values of 0.9 in predicting ensemble afferent signals may suffice to characterize their contribution (i.e., a higher accuracy would make very little difference to the overall performance of the overall neuromechanical model). On the other hand, the fine-tuning of locomotor phase transitions (from swing to stance and back) relies on accurate information on the position and velocity of a limb (Markin et al. 2010; Prochazka and Yakovenko 2007b), so here, a higher accuracy of the ensemble afferent input is desirable.

Models may be used in the future to infer movements and forces from ensemble firing rates recorded from dorsal root electrodes and to use these inferences to control muscle stimulators in real time. This inverse approach gave reasonably good estimates of muscle length and force from Ia and Ib ensemble firing rates reconstructed from individual recordings during locomotion (Prochazka 1999; Prochazka and Gorassini 1998b). Joint angles were estimated in real time from microelectrode array recordings of ensembles of muscle and skin afferents (Weber et al. 2007, 2011).

To what extent have the models been used in neuromechanical studies? Transfer function models of muscle spindles and GTOs have been used by several groups to analyze stretch reflexes (Poppo and Terzuolo 1968; Roberts et al. 1971; Rosenthal et al. 1970). Power-law function models have been used in several studies of reflexes and locomotion (Markin et al. 2010; Spardy et al. 2011a, b) (Dideriksen et al. 2011; Hatz et al. 2012; Prochazka and Sorensen 2009; Prochazka and Yakovenko 2007a, b; Shim and Husbands 2012; Stienen et al. 2007; Yakovenko et al. 2004; Zhang et al. 2009). Structural models have been used less often, partly because of their complexity and partly because they are more recent (Song et al. 2008a, b; Williams and Constandinou 2013).

Prosthetic Vision, Assessment

Lauren Ayton
Faculty of Medicine, Dentistry and Health Sciences, Departments of Optometry and Vision Sciences, and Surgery (Ophthalmology), Macular Research Unit, Centre for Eye Research Australia, The University of Melbourne, East Melbourne, VIC, Australia

Synonyms

Functional vision; Ultralow vision assessment; Visual function

Definition

As early-generation visual prostheses offer only modest increases in visual acuity, it is vital that a thorough assessment of pre- and postoperative function is completed. Assessment of prosthetic vision is multimodal and requires both clinical measures (visual acuity, visual fields) and functional vision measures (orientation and mobility, activities of daily living).

Detailed Definition

Assessment of prosthetic vision is challenging, as prosthesis recipients have very poor preoperative vision (less than 20/4000 or logMAR 2.3), and in early-generation devices, the improvements in vision are small. The majority of recipients of these early-generation prosthetic devices have a condition called retinitis pigmentosa (RP), and it is common for their visual performance to fluctuate significantly in differing light conditions. Due to these factors, a detailed and multimodal assessment of prosthetic vision is indicated and requires both clinical and functional vision measures.

Clinical Vision Measures

The main two clinical vision tests that are completed on prosthesis recipients are visual acuity and visual fields. Acuity gives a measure of a person's ability to see letter optotypes and gratings, as well as black-white discrimination and basic light perception. As the level of acuity experienced by the early implant recipients is very low, novel acuity tests have been developed to enable quantification of trace levels of function (Bach 1996; Bach et al. 2010; Bailey et al. 2012) (Fig. 1).

Functional Vision Measures

Due to the variability of results and difficulties in obtaining accurate clinical measures, it is important that assessments of prosthetic vision include functional vision testing. This includes orientation and mobility (O&M), which is a measure of how

Prosthetic Vision, Assessment, Fig. 1 Example of a novel visual acuity test developed for people with ultralow vision (less than 20/4000): the Berkeley Rudimentary Vision Test, which includes grating acuity (GA), basic functional vision (BFV), and single tumbling E letter optotypes (STE) (Image courtesy of Professor Ian Bailey, University of California – Berkeley). Visual field assessment for these patients requires a skilled examiner, as

people with RP often exhibit small and variable islands of residual vision. The most common method of assessing visual fields in recipients of visual prostheses is Goldmann manual kinetic perimetry (Bittner et al. 2011), in which a small illuminated target is moved slowly from the perimeter of the visual field until the patient reports seeing it. This enables the examiner to plot a map of any residual islands of vision (Fig. 2)

well a person can orientate themselves and move safely around an environment. O&M assessments can be simple, such as identifying a light in the room, through to complex tasks such as walking through a maze dotted with obstacles. In clinical trials of visual prostheses to date, O&M tasks have included following a line on the floor and identifying a black door on a white wall (Humayun et al. 2012).

The other key aspect in functional vision assessment is the testing of activities of daily living (ADLs). ADLs are tasks which are required for self-care and independent living and are considered to be key life skills. Examples of general ADLs are tasks such as cooking, getting dressed, and bathing. In relation to prosthetic vision assessment, researchers use ADL tasks which are vision-dependent, such as identifying common household objects and sorting light- from dark-colored laundry (Fig. 3).

Electrophysiology

Another method of assessing prosthetic vision is using electrophysiological methods.

Electroretinography (ERG) is a technique for measuring retinal responses to flashes of light and can give an indication of preoperative retinal function. Tests such as full-field stimulus threshold (FST) have been used to quantitatively measure levels of light perception in patients both pre- and postoperatively.

Methodology of Prosthetic Vision Assessments

Due to the fact that people with vision impairment often are able to compensate for their vision loss with other techniques (such as hearing, touch, and echolocation), it is important that the assessment of prosthetic vision includes adequate control scenarios. In visual prostheses that use an external camera, vision assessments can be made with the device on and device off (as a control). However, some devices do not have this ability and so require patients to be blindfolded during the control experiments.

Prosthetic Vision, Assessment, Fig. 2 A Goldmann perimetric plot, showing a small central island of residual vision in an otherwise blind visual field. The red and black lines represent different stimuli used in the test

Prosthetic Vision, Assessment, Fig. 3 Examples of activities of daily living: pouring a glass of water (a) and identifying common household objects (b)

To date, there has been no consensus into the methodology and reporting of assessments of prosthetic vision. It is hoped that this will eventuate in the coming years and result in generation of internationally accepted protocols for prosthetic vision testing.

Synonyms

Artificial vision; Bionic vision; Perceptual correlates; Subjective experience; Visual sensations of visual prostheses

Definition

Perceptual effects of prosthetic vision refer to the subjective experiences elicited by the use of a visual prosthetic device.

Detailed Description

General Appearance of Electrically Elicited Percepts

Visual prostheses that have been tested in human clinical trials are, as yet, invariably based on implanted devices that electrically stimulate the visual system. Most studies have focused on retinal implants, as opposed to cortical, optic nerve, and thalamic implants. Electrical point stimulation of visual nervous tissue can elicit localized flashes of light called phosphenes. Phosphenes generated by retinal stimulation are typically perceived as circular, oval, or ring-shaped spots of light (Rizzo 3rd et al. 2003; De Balthasar et al. 2008), but a variety of other shapes have been reported (Keserü et al. 2012). Typically they are white or yellow (Humayun et al. 2003), although other colors (Klauke et al. 2011) and “dark phosphenes” (i.e., darker than background) (Humayun et al. 2003; De Balthasar et al. 2008) have been reported as well. Dependent on stimulation

parameters, the angular subtense of phosphenes generally ranges from the size of a match head to a small coin viewed at arm’s length (Humayun et al. 2003; Rizzo 3rd et al. 2003).

Effects of Stimulus Parameters

Present-day implant systems encode light intensity by varying current level. The dependence of phosphene brightness on stimulus level can be described by a simple saturating power function (Humayun et al. 1996; Greenwald et al. 2009), and as many as 10 intensity levels may be distinguishable (Humayun et al. 2003). Increasing stimulus amplitude also increases current spread from the electrode, however, thereby impacting phosphene size (Humayun et al. 1996, 2003; De Balthasar et al. 2008; Nanduri et al. 2008, 2012; Wilke et al. 2011). Because of this, amplitude modulation may substantially decrease spatial resolution (Behrend et al. 2011). In contrast, pulse rate modulation has been shown to affect brightness while having little impact on phosphene size and may therefore be a more suitable approach for controlling phosphene brightness (Nanduri et al. 2012).

Single-point stimulation at different locations on the retina generally results in topographically organized phosphenes that roughly correspond to the retinotopic map (Rizzo 3rd et al. 2003; Humayun et al. 1996), e.g., stimuli applied in the upper-left hemisphere of the retina are perceived in the lower right of the field of view. Hence, by mapping images onto a retinal electrode grid, meaningful shapes can theoretically be presented to the implant wearer.

A particularly vexing issue in present-day retinal implants is the effect of fading, in which the brightness and size of phosphenes decline over time. Fading may occur within seconds after the onset of a train of stimulus pulses (Perez Fornos et al. 2012) but can take as long as 10 min to reach its full effect (Stronks et al. 2013). One way to reduce fading is to use low stimulation rates of 1–20 Hz. However, low stimulation rates of

1–5 Hz may result in unstable percepts (Stingl et al. 2013), since the flicker fusion frequency during single-electrode stimulation may be as high as 40–50 Hz (Humayun et al. 1999; Horsager et al. 2010). Hence, reduction of fading by adjusting the stimulation rate may cause a trade-off with perceptual image stability and intensity.

Performance of Visual Prosthesis Wearers

The Argus[®] II, alpha-IMS, and EPIRET3 clinical trials have shown that nearly 100 % of retinal-implant wearers benefit from their device when performing relatively simple tasks (e.g., identifying the orientation of a line, localizing a high-contrast target). 50–60 % benefit on more complex tasks (e.g., perceiving the direction of motion or “maze tracing”) (Humayun et al. 1999; Yanai et al. 2007; Klauke et al. 2011; Zrenner et al. 2011; Barry and Dagnelie 2012; Stingl et al. 2013). About 40–50 % of retinal-implant wearers can perceive large-print letters (in the order of 40° visual angle), while approximately 10–20 % are able to read short words (Zrenner et al. 2011; Da Cruz et al. 2013; Stingl et al. 2013). Single-letter recognition can take anywhere between 6 s and 3.5 min (Da Cruz et al. 2013). The drop in performance on more complex tasks can be attributed to many factors, of which spatiotemporal interactions between electrodes, retinal degeneration and remodeling, and a suboptimal tissue-electrode interface are among the most important (Marc et al. 2003; Horsager et al. 2010; Horsager et al. 2011).

Among the different implant systems tested to date, between-subject variability on standardized visual acuity tests is substantial. As much as 75 % of the subjects may not be capable of performing such tests (Da Cruz et al. 2013). For those who can, however, visual acuities as good as 20/546 have been reported (Stingl et al. 2013), a level classified as “profound vision loss.” This modest level of vision should be considered a huge achievement, since these patients were all classified as “functionally blind” before implantation.

Argus II subjects show significantly improved performance in orientation and mobility, including a task where they locate and walk to a high-contrast door and a task in which they follow a high-contrast line on the floor with different angles in it (Humayun et al. 2012). Hence, retinal implants can allow people previously unable to navigate without a guide dog or white cane to orient and navigate independently (Dorn et al. 2012).

Definition

An enzyme that phosphorylates proteins on either serine or threonine (a member of the serine/threonine kinase family) which is activated by cAMP.

Detailed Description

PKA is an abbreviation of protein kinase A, also known as cyclic adenosine monophosphate (cAMP)-dependent protein kinase (EC 2.7.11.11).

The studies of Krebs and Fischer (Krebs and Fischer 1956; Krebs et al. 1959) laid the foundation for protein phosphorylation as a mechanism for regulation, and PKA, discovered in the 1960s (Walsh et al. 1968), is viewed as a model kinase in the family of eukaryotic protein kinases (Taylor et al. 1993). PKA and PKA-dependent phosphorylation is also one of the key processes that regulate and engage in signaling pathways leading to synaptic plasticity (Nguyen and Woo 2003) and underlying learning and memory.

In the inactive state, PKA is composed of two regulatory (R) subunits (Gill and Garren 1969) forming a dimer and two catalytic (C) subunits. In fact, there are four different regulatory subunit isoforms (RI α , RI β , RII α , RII β). All four isoforms have a similar domain structure comprised of an amino-terminal dimerization/docking domain, two cAMP-binding domains at the carboxyl terminus (designated Site A and Site B, respectively; Doskeland 1978), and a linker region containing the primary docking/inhibitory site for the catalytic (C) subunit. The holoenzyme (R₂C₂) is activated by cAMP, which binds to the R-subunit; after which, the C-subunits dissociate from the inhibitory domains of the R-subunit dimer and these C-subunits are intrinsically active (Ogreid and Doskeland 1981, 1982; Herberg et al. 1996). The C-subunit is also inhibited by PKI (protein kinase inhibitor), a naturally occurring, high affinity inhibitor peptide (Walsh et al. 1990).

Based on the four cAMP-binding steps and the two C-subunit dissociation steps, Bhalla and Iyengar (1999) introduced a four-step cAMP-binding model with two-step PKAc dissociation:

The model and its rate constants were based on (Doskeland and Ogreid 1984; Ogreid and Doskeland 1981; Hasler et al. 1992; Smith et al. 1981) and can be found in the author's web

repository. This PKA model was incorporated into a model of four signaling pathways (Bhalla 2004a, b) which investigated effects of diffusion and scattering on information flow through four protein kinase regulatory pathways and investigated bistability, thresholding, and pattern selectivity in kinase regulatory pathways.

Though there are four cAMP-binding sites, Ogreid and Doskeland (1982) showed that protein kinase activity and cAMP binding comprise two nearly linearly coupled processes that are positively cooperative with a Hill coefficient of 1.7 (Zawadzki and Taylor 2004). Swillens (1983) discussed kinetic schemes that would fit data presented by Ogreid and Doskeland (1982) and allow minimal molecular requirements. Swillens (1983) then simplified a reaction diagram consisting of 15 holoenzyme states in order to obtain a minimal reaction scheme that fit the data from Ogreid and Doskeland (1982). Four possible reaction schemes were presented and fitted. One of these reaction diagrams, a two-step binding model, was used in (Kim et al. 2010). After binding four molecules of cAMP, the two catalytic subunits (C) dissociate from the regulatory subunit dimer (R):

The rate constants governing these biochemical reactions were fit to data in (Ogreid and Doskeland 1982; Zawadzki and Taylor 2004). This model explored why the requirement for PKA is limited to a long lasting form of long-term-potential (L-LTP) induced using spaced stimuli, but not massed stimuli. Simulations showed spaced stimulation activates more PKA than massed stimulation and made a key experimental prediction that L-LTP is PKA-dependent for intervals larger than 60 s. This prediction was confirmed experimentally (Kim et al. 2010). In a later paper (Kim et al. 2011), a two-step dissociation of R₂C₂(cAMP)₄ was added, based on the observation by Johnson et al. (1993) that the molecule R₂C₂(cAMP)₄ "opens up" and that binding of substrate stabilizes dissociation of the

C-subunit from the R_2 dimer. This PKA model was included in a multi-compartmental stochastic reaction–diffusion model. Simulations showed that PKA anchoring both near the source of cAMP and near specific targets enhance PKA activity; however, anchoring both near the source of cAMP dominates. Both models can be found in ModelDB database.

Graupner and Brunel (2007) presented a spike-timing dependent synaptic plasticity (STDP) model comprised of a biochemical model of the CaMKII autophosphorylation and the protein-signaling cascade governing CaMKII dephosphorylation, which included PKA. The activity of PKA by calcium–calmodulin activation of adenylyl cyclase was modeled using a Hill equation to condense several bimolecular and enzyme reaction steps:

$$v_{PKA} = k_{PKA}^0 + \frac{k_{PKA}}{1 + \frac{K_{PKA}}{C}},$$

where C is calcium–calmodulin concentration, k_{PKA}^0 is minimum PKA activity, k_{PKA} is maximum PKA activity, K_{PKA} is PKA half activity concentration, and n_{PKA} is PKA Hill coefficient. The model can be found in ModelDB database.

Due to its importance in synaptic plasticity, PKA activation has been incorporated into several other models (Zhabotinsky 2000; Lisman and Zhabotinsky 2001; Miller et al. 2005) as a parameter.

Definition

Protein kinase C is a class of protein kinases with 11 isozymes grouped into three

subclasses (Newton 2001). The protein kinase C isozymes in the typical group are activated by calcium, diacylglycerol (DAG), and arachidonic acid (AA). The isozymes in the novel group are activated by DAG and AA, but not calcium. The atypical group of isozymes are insensitive to both DAG and calcium. Most models of PKC activity describe binding of calcium and one or two lipids to the PKC holoenzyme.

Detailed Description

All of the protein kinase C isozymes have a similar catalytic domain, and most of the isozymes have two additional domains important for PKC activation: the C2 domain that binds two to three calcium ions and the C1 domain that binds lipids. One additional PKC isozyme is called PKM ζ . This is the constitutively active, catalytic domain of typical PKC. This molecule is normally at low levels, and it is “activated” either by cleavage of typical PKC forms or by synthesis.

Most, though not all, models of PKC activity are of typical PKC. These models differ by the reaction scheme describing PKC activation and also in the interaction of PKC with other signaling pathways. In addition, most PKC models are components of signaling pathways within the cerebellum, in part because PKC has demonstrated importance for long-term depression of excitatory synapses onto cerebellar Purkinje cells.

Conventional PKC: Bhalla Model

The first model of PKC activation in neurons was developed by Bhalla and Iyengar (1999), based on experiments showing that PKC is activated synergistically by calcium, DAG, and AA. In their model, AA could bind to any form of PKC (whether or not calcium or DAG was bound), and any order of binding was allowed:

Also, all bound forms of PKC were active, though an additional translocation to the membrane was required for forms not bound to AA. Calcium was not required for PKC activity; however, the PKC ligands acted synergistically, so that a much higher concentration of DAG and AA was required when acting alone. This model was originally implemented in Kinetikit (Bhalla and Iyengar 1999) and has been used in many signaling pathway networks.

This model was originally implemented in a feedback loop with MAPK and phospholipase A₂ (PLA₂) as illustrated in Fig. 1. Active PKC phosphorylates the small GTP binding protein Ras. PKC phosphorylation enhances the activity of the kinase Raf and PKC phosphorylation of RasGTP enhances its ability to activate Raf. Raf activates MAPK by phosphorylating MEK, which phosphorylates MAPK. The latter phosphorylates PLA₂, leading to higher production of AA, thus completing the feedback loop (Bhalla and Iyengar 1999). Simulations showed that this feedback loop exhibits bistability, a property important for long-term memory. Simpler models of PKC activation that omit the DAG binding also exhibit interesting dynamics when part of the same MAPK-PLA₂ feedback loop (Ajay and Bhalla 2007).

This reaction scheme also was used in several models of signaling pathways underlying LTD in cerebellar Purkinje cells. The amplitude of the synaptic response to parallel fiber input is controlled by the phosphorylation state of the AMPA receptors, and this amplitude is decreased (LTD) in response to paired climbing fiber and parallel fiber stimulation. In the first cerebellar LTD model (Kuroda et al. 2001), PKC phosphorylates AMPA receptors, whereas protein phosphatase

Protein Kinase C, Models of, Fig. 1 Positive feedback loop formed by PKC interacting with MAPK. PKC enhances activation of the monomeric GTP binding protein Ras, and activation of the kinase Raf, which phosphorylates MEK, which phosphorylates MAPK. Among its targets, MAPK phosphorylates phospholipase A₂ (PLA₂), which enhances production of AA, thereby further activating PKC. The feedback loop can be initiated by calcium acting on two molecules in the loop

2A dephosphorylates both MEK and AMPA receptors. Simulations showed that the initial phase of AMPA phosphorylation corresponded to the initial phase of PKC activation, which was independent of the MAPK loop. However, the intermediate phase of AMPA phosphorylation depended on the prolonged PKC activation provided by the MAPK loop. A combination of simulations and experiments evaluated whether the feedback loop could explain various characteristics of calcium dependence of cerebellar LTD, such as threshold behavior, cooperativity, and saturation. Indeed, once spatial gradients of calcium were taken into account, this feedback loop explained the sigmoidal relationship between calcium and LTD observed experimentally (Tanaka et al. 2007).

The feedback loop also has been incorporated into a signaling pathway model investigating hippocampal LTP (Kikuchi et al. 2003). This model included the dynamic regulation of protein phosphatase 2A by activated calcium

calmodulin-dependent protein kinase II (CaMKII) and was implemented in ECell. Simulations demonstrated that the additional reactions involving PP2A and CaMKII eliminate the need for PKC in producing LTP. Also this PKC feedback loop model, though with different rate constants, was used in a model of serotonin receptor activation of MAPK (Chang et al. 2009) via the HT1A receptor activation of MAPK through the guanine exchange factor mSos and the HT1A/HT2A receptor activation of MAPK through PKC.

Conventional PKC: Other Models

Kotaleski et al. (2002) developed an alternative model of PKC activation by calcium, diacylglycerol, and arachidonic acid. Imaging of translocation of both full length and various fragments of a GFP-tagged conventional PKC isoform (Oancea and Meyer 1998) suggests that calcium ions must bind first in order to expose the DAG binding site and that AA binding is required for a persistently active form. This led to a sequential model of PKC activation:

This model was used in a model of LTD in cerebellar Purkinje cells and illustrated that PKC activation was sensitive to timing of parallel fiber and climbing fiber activation. Interestingly, the main source of timing sensitivity was not due to PKC binding order, but was due to temporal sensitivity of IP₃-induced calcium release.

This model also was used in a spatial model of LTD in the medium spiny neurons of the striatum (Kim et al. 2013). Simulations demonstrated that the translocation of PKC from the cytosol to the membrane could be explained as a passive process that resulted from binding of the calcium bound PKC to the DAG in the membrane.

More recently, the Bhalla model of PKC has been updated (Antunes and De Schutter 2012) based on recent evidence of multiple calcium

binding sites: one high affinity site (1 μM) and another two sites which affinity ranges from 4 to 22 μM (Torrecillas et al. 2004). Binding of three calcium ions promotes PKC binding to membrane phospholipids, and arachidonic acid acts synergistically with calcium to promote translocation and binding to membrane phospholipids such as DAG, though this latter binding step was not modeled explicitly. This updated model was implemented within the MAPK/PLA₂ feedback loop and simulated stochastically to investigate threshold behavior and sigmoid response characteristics of cerebellar LTD.

Other PKC Isozymes

There are only a few models of other forms of PKC. There is one model of novel PKC, which is sensitive to DAG, but not calcium (Dupont et al. 2011). This model was used to investigate calcium oscillations caused by stimulation of the type 5 metabotropic glutamate receptor (mGluR5). The overall goal of that study was to develop a minimal model which could explain experimental results of calcium oscillations. Consequently, PKC activation was a sigmoid function of DAG concentration, with maximal rate of K_{act} and half activation of K_{DAG} :

$$\frac{d\text{PKC}}{dt} = K_{\text{act}} \cdot \frac{D}{D + K_{\text{DAG}}} \cdot (1 - \text{PKC}) - K_{\text{deact}} \cdot \text{PKC} \quad (3)$$

The DAG to activate PKC was produced by the activated mGluR5 receptor, and the activated PKC in turn phosphorylated the mGlu5 receptor which caused cessation of DAG and IP₃ production. Simulations show that this negative feedback loop produces calcium oscillations due to the periodic IP₃ production and thus is an alternative mechanism to that typically modeled in response to constant IP₃.

Two models of PKM ζ have been developed to investigate mechanisms underlying the persistence and maintenance of synaptic plasticity. One model added PKM ζ to the Bhalla PKC-MAPK/PLA₂ feedback loop model to

investigate mechanisms underlying the late phase and consolidation phase of cerebellar LTD (Ogasawara and Kawato 2009). In this model, the PKM ζ is activated initially by MAPK; then the PKM ζ activates itself by inducing its own translation. Simulations show how the PKM ζ positive feedback loop supports the late phase of LTD and memory consolidation, which is disrupted by protein synthesis inhibitors.

A second model of PKM ζ investigated its role in synaptic tagging and capture (Sajikumar et al. 2005), which describes the observation that strong stimulation in the hippocampus is needed to produce a protein synthesis-dependent, long-lasting LTP or LTD, but that a weak stimulation is converted to a long-lasting LTP or LTD if given within 30 min or so of the strong stimulation. In this two-compartment model (Smolen et al. 2012), synthesis of PKM ζ in the dendrite required phosphorylation of (unknown) targets by both CaMKII and MAPK. PKM ζ can diffuse into the spine compartment to cause LTP. Model simulations showed that LTP maintenance was caused by bistability in PKM ζ activity in the spine compartment.

PSICS (www.psics.org, Cannon et al. 2010) is a simulator for computing the behavior of neuron models in which the membrane ion channels are

expressed as kinetic schemes. It can operate in the stochastic regime where each channel is treated as an independent entity or in the deterministic regime where a population of channels is lumped together as a single continuous process. For extended cells, channels are given precise positions on the membrane before any spatial discretization is performed so exactly the same model can be computed at different spatial and temporal resolutions and with the various channel populations computed stochastically or deterministically. This enables a range of questions to be addressed concerning the influence of channel stochasticity and spatial discretization on the behavior of neurons.

Detailed Description

PSICS operates as a sequential processor taking a declarative model description as input and mapping it through a series of processing and computation stages to produce a self-contained set of data tables, images, logs, and XML files linked by an HTML index file as output. The input files must specify the model, the simulation to be performed, and the quantities to be recorded. There are no command line options and it does not have a graphical user interface. The complete input specification is packaged up as a zip file as part of the output results set so that any PSICS computation can be reproduced from its results set.

The main stages of a PSICS simulation are:

- Model instantiation. Each ion channel is given an exact position on the membrane.
- Discretization. The 3-D morphology is divided into sections by perpendicular cuts across straight sections of the structure. Cuts are not made at branch points.
- Tabulation of kinetic schemes. For each channel type, the finite-time step transition matrix is tabulated over a grid of membrane potentials.
- Serialization. The transition matrices, element dimensions, numbers of channels of each type per element, stimulation parameters, and recording configuration are written out as a single space and newline delimited ASCII file.

- Execution. A separate process reads just this ASCII file and performs the specified calculations, comprising mainly channel population updates and membrane potential diffusion.
- Output and rendering. The results of the execution step are used to generate any figures specified in the initial model specification, and these are combined into a single web page incorporating the model description, figures, and raw output.

For all but the shortest simulations, the execution step is the dominant computational cost. Two implementations are provided for this stage: one written in Java and the other in highly optimized Fortran. All other steps are implemented in Java. For stochastic calculations of a population of channels on an isopotential element, PSICS exploits the interchangeability of channels in the same state. Rather than storing the state of every channel, it is sufficient to know how many channels there are in each possible state. Furthermore, at most membrane potentials, the overwhelmingly most likely outcome for any channel over one time step is that it will be in the same state at the end of the step as it was at the beginning. PSICS exploits this observation to allow approximate stochastic population updates with far fewer random numbers and operations than would be required if every channel is treated independently. A range of heuristics and fitting functions is used to ensure the statistical properties are within the required tolerance over a range of population sizes and transition probabilities.

Pulse-Coupled Oscillators

Carmen C. Canavier

Department of Cell Biology and Anatomy, LSU Health Sciences Center, New Orleans, LA, USA

Definition

Pulse-coupled oscillators are intrinsically rhythmic circuit elements (oscillators) that are coupled via instantaneous interactions. Pulse (or pulsatile) coupling is only approximate because real world pulses cannot exert their effects instantaneously. Instead, a finite amount of time must elapse in order to produce an effect. However, the theoretical results for pulse-coupled oscillators generally apply to cases in which the input pulse exerts its effects during a time window of finite duration, provided that this duration is short compared to the period of the oscillation.

Detailed Description

This article focuses on neural oscillators, or intrinsically rhythmic nerve cells (neurons). Neurons are well suited to an analysis based on pulse coupling because they communicate via action potentials, also called spikes, which are all or nothing electrical signals that trigger a cascade of events leading to a somewhat slower, graded response in the target neuron. Coherent oscillations in networks of neurons are thought to coordinate the flow of information necessary for cognitive processing (Wang 2010). Phase locking implies a consistent phasic relationship between periodic events. Phase locking between spikes and a periodic drive or between spikes in mutually coupled oscillators can be investigated using pulse-coupled oscillator theory. These phasic

relationships may be utilized for information processing (Buzsaki 2006). Other oscillatory systems, such as fireflies emitting a pulse of light (Pikovsky et al. 2001) or central pattern generating circuits comprised of bursting neurons (Canavier 2005), have also been analyzed using the same pulse-coupled methods. Phase locking in central pattern generators may be important for coordination of rhythmic motor activity (Glass and Mackey 1988).

Networks of coupled oscillators can be studied analytically using simple integrate-and-fire networks or by numerical simulations of specific networks; both of these methods produce results that are model dependent. Model-independent results can only be obtained by assuming rather severe limitations in the case of weak coupling or pulsatile coupling (Ermentrout and Chow 2002; Izhikevich 2007). The model-independent nature of the results obtained from pulsatile coupling stems from the assumption that the oscillators involved are limit cycle oscillators (Winfree 2001; Glass and Mackey 1988). In mathematical terms, the periodic trajectory in a multi-dimensional state space must be a stable limit cycle, that is, a closed, periodic trajectory to which all nearby trajectories in a nonlinear dynamical system are attracted in the limit of long times. This article focuses on the model-independent results that can be obtained using pulsatile coupling when the effect of that pulsatile coupling on the component oscillators is not constrained to any particular form. However, very influential results that were obtained for a particular form of pulsatile coupling between generalized integrate-and-fire model oscillators will also be presented because of the historical importance of the analytically tractable integrate-and-fire models.

Event Maps

The analytical approach to pulse-coupled oscillators in general consists of constructing a map of events, meaning that the timing of previous events is used to calculate the timing of future events. The emission of a pulse by one oscillator and its

receipt by another are the critical events in map construction. If conduction delays between oscillators are ignored, the difference in elapsed time between the time of emission and the time of receipt is considered to be small and neglected. The intrinsic rhythmicity of an oscillator is necessary for this analysis. In addition, a threshold event that precipitates emission of a pulse by each oscillator in order to influence the other oscillators is required. Uncoupled oscillators emit pulses, which we will call spikes without loss of generality, at regular intervals given by the free running period T_0 . Therefore, for a single uncoupled oscillator (Fig. 1a), the time of the next spike can be obtained by adding the cycle period T_0 to the time at which the previous spike occurred. Each cycle of the free running cycle is presumed to be identical, so the time elapsed since the previous spike at the time the stimulus is applied corresponds to a unique point in the cycle, called the phase θ . The phase in Fig. 1 is the elapsed time normalized by the cycle period and ranges from zero to one, but other choices for normalization are possible. If an oscillator receives a pulsatile stimulus during a particular cycle (Fig. 1a, arrow), then the perturbed cycle length is shortened by an amount $\Delta T(\theta)$ that depends upon the time elapsed since the previous spike (if the period is lengthened the convention adopted here is that $\Delta T(\theta)$ is negative). The effect of the coupling depends upon the phase at which pulses are received, and this dependence is quantified as a phase-resetting curve of arbitrary shape (Glass and Mackey 1988; Schultheiss et al. 2012). The main assumption of pulse-coupling theory is that only the cycle that contains the perturbation is altered in duration and that the free running rhythm is reestablished immediately after the spike following the perturbation (Winfree 2001; Glass and Mackey 1988). For the coupling to be effectively pulsatile, the attraction to this limit cycle must be strong enough for each oscillator to ensure that the effects of perturbations decay quickly. So if the inputs are delivered too often, or the attraction to the limit cycle is too weak, or the stimulus is too strong, an analysis based on pulsatile coupling and event maps can fail (Izhikevich 2007).

Event Map for Periodic Pulsatile Forcing

An event map can be formulated for periodic forcing of an oscillator. In the example given in

Fig. 1b, a pulsatile stimulus is applied repetitively at forcing intervals T_F . In this example, the elapsed time since the previous spike at the time an input is received converges to a steady value such that the forced oscillator becomes phase locked to the periodic stimulus. The forcing stimulus provides a reference point for stroboscopically sampling the forced oscillator. A potentially huge reduction in the dimensionality of the system is achieved by sampling a scalar quantity, the phase of the forced oscillator, each time that a forcing pulsatile stimulus is applied. A map that gives the phase of the oscillator at the time of one input in terms of the phase at the previous input can be constructed based on the algebraic relationships evident in the diagram at the top of Fig. 1c. This diagram assumes a one-to-one ratio of input stimuli to oscillator spikes. Forcing at a 1:M ratio can be analyzed by assuming M unperturbed oscillator periods between input stimuli rather than just one (Rinzel and Ermentrout 1998).

For the one-to-one ratio shown, the key observation is that the sum of the perturbed cycle ($T_0 - \Delta T(\theta[n])$) and the elapsed time ($T_0\theta[n+1]$) to the stimulus on cycle $n+1$ represents the same time interval as the sum of the elapsed time ($T_0\theta[n]$) to the stimulus on cycle n and the forcing period (T_F). Therefore, subtracting $T_0 - \Delta T(\theta[n])$ from both sides of the equality and dividing through by T_0 produces the event map $\theta[n+1] = f(\theta[n]) = \theta[n] + T_F/T_0 - 1 + \Delta(\theta[n])$, where $\Delta(\theta[n])$ is the normalized phase-resetting $\Delta T(\theta[n])/T_0$ (Glass and Mackey 1988) and $f(\theta[n])$ is the map from the phase on one cycle of forcing to that on the next. Note that there are two components to the map: the resetting term that occurs at the time of the pulse ($\Delta T(\theta[n])/T_0$) and the detuning term ($T_F/T_0 - 1$) that accounts for the change in phase (modulo one) that occurs during a forcing period. The dependence of the “old” phase prior to a pulse and the “new” phase immediately after a pulse is given by the phase transition curve (Glass and Mackey 1988). The map can also be written in terms of the “new” phases after the pulse (Pikovsky et al. 2001, p. 64), rather than the “old” before the pulse as shown above. Both maps are Poincare phase maps on a circle (Izhikevich 2007; Pikovsky et al. 2001; Winfree

2001), since the phases 0 and 1 represent the same point.

Poincare maps offer an important advantage in the study of dynamical systems, in that the stability of a periodic orbit in a system of differential equations reduces to the problem of the stability of the corresponding fixed point of the map (Wiggins 1990, Chap. 1). The forced oscillator phase locks to the stimulus if $\theta[n+1] = \theta[n] = f(\theta[n])$, which occurs when $f(\theta)$ intersects the diagonal (dashed line in Fig. 1c1–4). For simplicity of notation, we will omit the indexing of the phases in the remainder of the map descriptions. The map is iterated graphically by starting at a value of θ on the diagonal, moving vertically to the $f(\theta)$ curve to find the next value of θ , then returning to the diagonal horizontally and repeating. Linearizing the map shows that a periodic locking is stable if the absolute value of the slope of $f(\theta)$ is less than one. This is clear from the schematic drawings in Fig. 1c. For a stable node (Fig. 1c1), $0 < f'(\theta) < 1$, and the phase monotonically converges to its steady value as in Fig. 1b. For a stable focus (Fig. 1c3), $0 > f'(\theta) > -1$, and the phase alternately increases and decreases until it reaches its steady value. For an unstable node (Fig. 1c2), $f'(\theta) > 1$, and the phase monotonically diverges in the vicinity of the intersection. For an unstable focus (Fig. 1c4), $f'(\theta) < -1$, and the phase alternately increases and decreases as it diverges in the vicinity of the intersection. The stability criterion can equivalently be written in terms of the phase-resetting curve (Rinzel and Ermentrout 1998) so that $-2 < \Delta'(\theta) < 0$ at the fixed point guarantees stability.

Event Map for Two Pulse-Coupled Oscillators

An event-based map can also be constructed for two pulse-coupled oscillators firing in alternation (Ermentrout and Terman 2010, pp. 193–194; Pikovsky et al. 2001, Chap. 8). For the case of two pulse-coupled intrinsic oscillators with no external forcing, the stroboscopic Poincare sampling occurs at the time of each internally generated threshold event. The assumption of identical,

identically coupled oscillators allows the double iteration (Fig. 2) of a single event map (Pikovsky et al. 2001, Chap. 8) in terms of the phases and the phase-resetting Δ normalized by the intrinsic period T_0 . Time can be removed from the map since both oscillators have the same intrinsic period. Figure 2a schematically shows the timing of threshold events (spikes) in two coupled

oscillators that lead to the emission of a pulse that affects the other oscillator. Figure 2b shows the presumed time course of the phases. The phase increases at a constant velocity between threshold events. When the phase in one neuron reaches one, its phase is reset to zero, and the phase of the other oscillator is instantaneously incremented or decremented as a result of the pulse coupling.

Stroboscopic phase map for pulse-coupled leaky integrate-and-fire neurons, whose PRC is given in the inset. Arrows show that the intersection of the smooth part of the map with the diagonal is unstable, and synchrony at phases 0 and 1 is globally attracting

There are two steps in constructing the event-based map, updating the phases (1) immediately after a pulse and (2) during the interval until the next pulse in the other neuron. Figure 2a, b shows the double iteration of the map starting at the phase just prior to a spike in the red neuron.

This event stroboscopically samples the phase θ of the black neuron at the point just prior to the pulse, indicated schematically with a black circle containing the label 0. The phase is updated to the phase just after the pulse is received ($\theta + \Delta(\theta)$) by adding the resetting appropriate for the phase at which the pulse is received. This first step in the first iteration is schematically indicated by a black circle containing the label 1a. Since the red neuron had a phase of zero at the time just after the pulse, the normalized interval ($1 - \theta - \Delta(\theta)$) that remains until the next spike in the black neuron occurs becomes the phase just before the next pulse is received in the red neuron. This second step in the first iteration is indicated schematically by the red circle containing the label 2a. This iteration can be described by the intermediate mapping $h(\theta) = (1 - \theta - \Delta(\theta))$. Since the two neurons are identical and identically coupled, the same two steps are repeated for a second iteration. The dependence of the phase of the reference oscillator on one cycle as a function of its phase on the previous cycle is $f(\theta)$, where $f(\theta) = h(h(\theta))$. Thus, the phase $\theta[n + 1]$ just prior to a pulse received by the black neuron can be written in terms of the phase $\theta[n]$ just prior to the previous pulse as follows: $\theta[n + 1] = f(\theta[n]) = \theta + \Delta(\theta) - \Delta(1 - \theta - \Delta(\theta))$. Therefore, a map analogous to those shown in Fig. 1c can be constructed for two identical pulse-coupled oscillators as shown in Fig. 2c. Sometimes this map is constructed using time rather than phase and called a spike time difference map (Canavier and Achuthan 2012). The derivation for the map in Fig. 1c was given in terms of the algebraic relationships between time intervals, whereas the map in Fig. 2c was derived explicitly applying the map to the presumed time course of the phases, but the two approaches are equivalent, and either can be applied. Again, $|f'(\theta)| < 0$ is required at the intersection of $f(\theta[n])$ with the diagonal in order for the fixed point at that intersection to be stable.

Applying the chain rule shows that the following quantity written in terms of the slope of the phase-resetting curve $(1 + \Delta'(\theta))(1 + \Delta'(1 - \theta - \Delta(\theta)))$ must have an absolute value less than one for stability.

The map $f(\theta)$ in Fig. 2c is shown for the case of two identical pulse-coupled leaky integrate-and-fire oscillators with the phase-resetting curve for the pulses shown in the inset. In this case the map $f(\theta)$ has a monotonically increasing portion. Any fixed point in this interval is given by the intersection with the diagonal (dashed line) and is unstable because the slope is greater than one. The flat portion of the map indicated by the thick arrows at the top and bottom results from the form of the pulse coupling: if one oscillator fires a sufficient short interval before the other, it causes the other oscillator to fire at the same time and they remain synchronized. The map in Fig. 2c makes the assumption that one neuron never fires two consecutive spikes before the other neuron has a chance to fire. More complicated maps can be constructed for other scenarios (Canavier and Achuthan 2010).

One method for obtaining general results is to use an analytically tractable model, like a leaky integrate-and-fire model; such a model has an observable (usually membrane potential) that increases monotonically between threshold events and is reset to its minimum value after reaching its threshold value. A very influential treatment of the two-oscillator problem by Mirollo and Strogatz is described in Pikovsky et al. (2001) as well as in Ermentrout and Terman (2010). This approach generalizes the leaky integrate-and-fire model, in which v is the only observable variable. They assume that the time evolution of v on each cycle is a function $g(\theta)$ of the elapsed time, which in this case is proportional to the phase (θ), and that the function $g(\theta)$ is monotonically increasing $g'(\theta) > 0$ and concave $g''(\theta) < 0$. The pulse coupling has the form that a pulse in one oscillator increases v in the other oscillator either to $v + \varepsilon$ or to the firing threshold, whichever is less.

Under these assumptions, it can be shown directly that there is a single unstable attractor and that it repels all trajectories that do not lie on

this fixed point toward synchrony. For two identical oscillators, it is enough to show that the slope of just one iteration of the previously derived map $h(\theta) = (1 - \theta - \Delta(\theta))$ has an absolute value greater than one due to the symmetry. The phase at the point labeled 1a in Fig. 2b, just after the black neuron receives an input is $g^{-1}(v + \varepsilon)$, where g^{-1} is the inverse function and v is the voltage just prior to the pulse. Then the phase at the point labeled 2a for the phase in the red neuron just prior to the next spike in the black neuron is $h(\theta) = 1 - g^{-1}(g(\theta) + \varepsilon)$. The derivative $h'(\theta) = -g'(\theta) g'^{-1}(g(\theta) + \varepsilon)$, which can be rewritten as $h'(\theta) = -g'^{-1}(g(\theta) + \varepsilon)/g'(\theta)$, taking advantage of the fact that the two functions are inverses. The fact that $g''(\theta) < 0$ implies that $g'^{-1}(\theta) > 0$, so it follows that the absolute value slope of $h(\theta)$ and therefore of $f(\theta)$ is greater than one everywhere on the smoothly varying segment, and therefore any intersection with the diagonal in the monotonically increasing portion of the map is unstable as indicated. The pulse-coupled leaky integrate-and-fire model satisfies their assumptions; therefore, the Mirollo and Strogatz results apply as shown schematically in Fig. 2c. Since it is also true that $h'(\theta) = -1 - \Delta'(\theta)$ on the continuous segment, the proof is exactly equivalent to showing that the smoothly varying portion of the PRC is monotonically increasing ($\Delta'(\theta) > 0$). The flat portion of the map that synchronizes immediately is due to the second segment of the PRC that is linear with a slope equal to -1 . The shape of the map guarantees that there is but a single intersection of the smoothly varying portion with the diagonal.

For two nonidentical oscillators, symmetry is broken, but a single map still captures the dynamics. The intrinsic periods T_1 and T_2 , the stroboscopically sampled phases θ_1 and θ_2 , and the normalized phase-resetting curves Δ_1 and Δ_2 are subscripted to indicate that they may be different for the two neurons. Since the oscillators have different frequencies, we must explicitly keep track of time intervals and not just phases. The information in the phase-resetting curve is not sufficient; we need the information from the spike time resetting curve that preserves the time interval information. Figure 3a shows the

Pulse-Coupled Oscillators, Fig. 3 Two nonidentical oscillators. (a) Schematic showing firing intervals τ . (b) Stroboscopic map of the firing intervals shows the intersection at the lower right is stable

derivation from Ermentrout and Terman (2010) of the map for two nonidentical pulse-coupled oscillators. The interval between the firing of the first neuron (black) and the second (red) is designated τ_1 , whereas the firing interval between the second and first neuron is τ_1 . In the drawing the firing intervals and stroboscopically sampled phases are indexed by cycle number. These intervals can be calculated in two ways: based on the phase in the non-firing neuron at the end of the interval, as in $\tau_1[n+1] = T_1 \theta_1[n]$ and $\tau_2[n] = T_2 \theta_2[n]$. Alternatively, the intervals can be calculated based on the phase at which the firing neuron previously received an input, as in $\tau_1[n+1] = T_2 - T_2 \theta_2[n] - T_2 \Delta_2(\theta_2[n])$ and $\tau_2[n] = T_1 - T_1 \theta_1[n] - T_1 \Delta_1(\theta_1[n])$. After substitution, the interval map is $\tau_1[n+1] = T_2 - T_1 + \tau_1[n] + T_1 \Delta_1(\tau_1[n]/T_1) - T_2 \Delta_2(1 - \tau_1[n]/T_2 - \Delta_1(\tau_1[n]/T_2))$, and a one-dimensional map similar to the

one in Fig. 2c can be constructed in which the intersections with the diagonal give the fixed point. An alternate map construction is given in Fig. 3b that shows the intervals in both neurons rather than just one, using the fact that each interval can be calculated either in terms of the previous phase in the one neuron $\tau_j = T_i - T_i \theta_i - T_i \Delta_i(\theta_i)$ or in terms of the current phase in the other $\tau_j = T_j \theta_j$. The black curve calculates the intervals using the phase in the black neuron, and the red curve calculates the intervals using the phase in the red neuron. The intersections of the two curves are the fixed points of the map which correspond to phase-locked period modes of the two-oscillator system. If the frequencies of the oscillators are sufficiently different, there will be no intersection and no one-to-one phase-locked mode. The arrows show the stroboscopic sampling: the leftmost intersection is unstable, but the rightmost intersection is stable. The stability criterion can be obtained by taking the derivative with respect to phase of the map given above for $\tau_1[n+1]$ in terms of $\tau_1[n]$. The resultant criterion is that $-1 < (1 + \Delta_1'(\theta_1))(1 + \Delta_2'(\theta_2)) < 1$, the same as for two identical oscillators except the relationship between the two phases θ_1 and θ_2 is slightly more complicated than in the homogeneous case.

More Complicated Systems

We have shown in detail pulse-coupled maps for one-to-one forcing of a single oscillator or one-to-one phase locking between two oscillators. These methods are generalizable to many more complicated cases (for a review, see Canavier and Achuthan 2010, 2012). For example, including conduction delays in a circuit of two pulse-coupled oscillators can change not only the phasic relationships between the oscillators but also the stability criterion. They can be extended to M:N locking in two-neuron networks. Pulse-coupling methods have also been applied to study more complex architectures, such as globally coupled synchronous networks and multiple clusters of synchronous neurons within networks, chains, rings, and hubs.

The Fully Synchronous State of Mirollo and Strogatz

The reason the Mirollo and Strogatz approach was so influential was because it could be extended to an N neuron network to show the global attractiveness of the fully synchronous state of a network of all-to-all identical, identically pulse-coupled oscillators under their assumptions. An $N - 1$ dimensional map (Guckenheimer and Holmes 1983, Chap. 1) was constructed for an N neuron network of identical, identically all-to-all coupled neurons by indexing the oscillators by the time until the next spike in that oscillator, which rotated in a predictable manner on each cycle and did not require a map for the currently spiking oscillator. The all-to-all coupling assures that each neuron receives the same inputs as every other neuron. The map uses the same general approach shown in Fig. 2 with the same two steps in the reverse order. After any oscillator fires, the phase of every oscillator is updated by the interval until the next oscillator indexed $N - 1$ in the rotation fires, then the phase of every oscillator is updated by the phase resetting produced by that event such for each oscillator i . This produces the set of maps $h(\theta_i) = g(g^{-1}(\theta_i + 1 - \theta_{N-1}) + \epsilon)$. The predictability of the firing order resulted from the assumption of a common intrinsic frequency and the monotonically increasing $g(\theta)$ and the form of the coupling. Under these assumptions, if the phase of an oscillator is less than that of another before they receive a common input, it is still less (or equal) after the two oscillators receive a common input. The $N - 1$ dimensional map is only defined for sequential firing patterns, and Mirollo and Strogatz proved in a manner analogous to the two-neuron case that any fixed point of this map must be unstable. However, there are other possible firing patterns because the phases of two oscillators can become equal if the firing of one oscillator brings another to threshold; after the spike, both oscillators are reset to a phase of zero. From that point forward, the two oscillators, which have the same frequency, receive exactly the same input and therefore have identical dynamics for all time. This event is called an absorption. Therefore, they

must also show that no firing patterns with partial absorptions can persist. The map was redefined after each absorption: neurons that have been synchronized are considered to coalesce into a single oscillator with a greater pulse strength. Thus, the number of independent oscillators is reduced. The proof does not depend on the pulse strengths being equal but instead only requires at least one pulse strength to be nonzero to destabilize the sequential state comprised of the redefined set of oscillators. Therefore, all sequential states in which some but not all neurons fire together are unstable, and global synchrony is therefore globally attracting.

The Fully Synchronous State of Goel and Ermentrout

The globally attracting, global synchrony described above is very dependent on the form assumed for the voltage waveform and the pulsatile resetting. Goel and Ermentrout used the same methodology to construct return maps for networks of all-to-all connected oscillators with identical frequencies; however, they made no assumptions regarding the voltage waveform or the precise form of the pulsatile coupling. For two neurons, the stability of synchrony can be determined by evaluating the criterion for stability in an alternating firing pattern at the phases just after (phase = 0^+) and just before (phase = 1^-) a spike, so that synchrony is stable if $-1 < (1 + \Delta'(0^+))(1 + \Delta'(1^-)) < 1$. The slopes of the phase-resetting curves are often not the same just after a spike and just before a spike for a variety of reasons, hence the right limit at a phase of 0 and the left limit at a phase of 1. This concept was extended to N all-to-all coupled neurons as follows. The phase transition function $F(\theta)$ was defined (Glass and Mackey 1988) as the phase after a pulse as a function of the phase immediately before a pulse: $F(\theta) = \theta + \Delta(\theta)$. They required $F(\theta)$ to be monotonically increasing in order to ensure the preservation of the sequential firing order. They excluded the possibility that a pulse could immediately bring an oscillator to threshold, meaning that

absorptions were excluded or at least assumed to occur all at once or not at all. These assumptions put the problem of global synchrony in a much different context than Mirollo and Strogatz, because the map of the alternating firing pattern was not applied to sequential firing patterns that repelled trajectories toward global synchrony. Instead the map was considered as a perturbation from global synchrony, and if the perturbation can be shown to die out, then global synchrony was considered stable. The issue of whether stability is globally attracting is not addressed by this methodology.

The map was constructed based on the PRCs, using the steps shown in 2a and 2b of Fig. 2b, with a rotating frame of reference so that the phase of each neuron was updated between pulses using the time until the next neuron to fire will reach threshold, then updated again by the phase resetting due to the most recent pulse. The neurons were indexed in the order in which they will fire next, so the indexes were also updated after each spike. The stability of the coupled map system was determined by linearizing about the fixed point and calculating the eigenvalues of the system. For a system in which the slopes at 0 and 1 are the same, then the stability criterion reduced to $-1 < F'(0) < 1$, or $-2 < \Delta'(0) < 0$, but $F'(0)$ was already assumed to be greater than zero because of the assumption that it is monotonically increasing. On the other hand, if the slope is discontinuous, then the stability criterion requires all permutations of $F'(0)^L F'(1)^{N-L}$ to have an absolute value less than 1. The stability of synchrony can depend on network size. A more general approach would consider perturbations with arbitrary numbers of neurons forming synchronized clusters, as in Mirollo and Strogatz.

Direct Extension of Two-Neuron Method for Synchrony

The Mirollo and Strogatz approach allowed for the possibility that a group of oscillators have a stronger effect on other oscillators than a single oscillator. They also neglected any effect of

coupling within a group of synchronized oscillators. Extending the two-neuron stability criterion for synchrony to groups of arbitrary size within an all-to-all N neuron network results in the set of criteria $-1 < (1 + \Delta_L'(0^+))(1 + (\Delta_{N-L}'(1-))) < 1$ for $L = 1$ to $N - 1$, where the subscript refers to the phase resetting due to groups of L and $N - L$ synchronized neurons, respectively (Achuthan and Canavier 2009). There is clearly an effect of network size in these criteria as well, and in that study, that perturbing a single neuron was likely to be the most destabilizing perturbation.

Applying Pulse-Coupled Maps to Real Neural Systems

There are two basic ways in which the pulse-coupling assumptions are violated by physical systems: (1) multiple input pulses that are not sufficiently separated from each other or (2) input pulses that have effects that continue beyond the next pulse emitted by the receiving oscillator. Also, it is likely that strong pulses do not sum linearly. In an N neuron network, an individual neuron may receive pulses from many other neurons. If they are spaced together closely in time, the neuron may not be able to recover from one pulse before the next is received, violating the pulse-coupling assumptions. In a physical system, the effects of two sequential pulses that are applied with diminishing separation must converge to the effect of two simultaneous pulses, but if the two pulses do not add linearly, a discontinuity appears in the pulse-coupled approximation. A second way that the assumption can be violated is if a single pulse affects not only the duration of the cycle in which it is received but the next cycle as well. This can happen if there is insufficient time to recover to the limit cycle before the neuron spikes. Also, real inputs are not Dirac delta functions with no width but instead have a finite duration. Therefore, pulses applied near the end of one cycle may bleed over into the next. The effect on the next cycle has been called second-order resetting and complicates stability criteria by requiring higher dimensional maps (Canavier and Achuthan 2010, 2012). If the resetting at zero phase is

nonzero, the presence of second-order resetting can cause the first-order resetting, or the effect on the cycle that contains the pulse, to appear discontinuous, that is, to have different values at phases of 0 and 1. Finally, the map approaches described assume a particular firing pattern, then analyze that pattern only. More generally, pulse-coupled maps (Canavier and Achuthan 2010, 2012) can be constructed by simply polling all oscillators and updating the phases based on the time till the next threshold event, but this general map is not analytically tractable. Despite these limitations, pulse-coupled maps have been used to explain synchrony within local networks of neuron as well as between distal brain regions (Ermentrout and Terman 2010).

Pulse-Resonance Sounds

Roy D. Patterson
Department of Physiology Development and Neuroscience, University of Cambridge, Cambridge, UK

Synonyms

Animal calls; Engine purr; Musical tones; Speech sounds

Definition

Pulse-resonance sounds are the sounds that animals use to communicate at a distance, to declare

their territories, and to attract mates (Fitch and Reby 2001). They form the basis of most of the calls produced by vertebrates (fish, frogs, birds, and mammals). The tones of orchestral instruments are pulse-resonance sounds (Fletcher and Rossing 1998) and the internal combustion engine produces a form of pulse-resonance sound. Pulse-resonance sounds are ubiquitous in the world around us and they are the interesting sounds of everyday life (Patterson et al. 2008). They are acoustically distinct from the inanimate sounds produced by turbulent air and water (wind and rain).

Detailed Description

The vowels of speech are pulse-resonance sounds and the waveforms of the vowels illustrate the properties of these sounds. Figure 1 shows the waveform (a) and the magnitude spectrum (b) of an /a/ vowel. It sounds like the vowel in the word “paw” and in this case it sounds like it was spoken by a child. Note that the period of the sound is very short (5 ms); six cycles of this sound would occur in less than the time of a single frame of a standard video. So the waveform in this figure presents the microstructure of the sound.

Under this temporal microscopic, we see that the sound is composed of a regular stream of acoustic pulses, each of which is accompanied by a resonance. It is this pairing of pulses with resonances and the mechanical implications for how the sounds are produced that gives them the name *pulse-resonance sounds* (Patterson et al. 2008).

Pulse-Resonance Sounds and Source-Filter Systems

The mechanisms in animals and musical instruments that produce pulse-resonance sounds are referred to in engineering terms as *source-filter systems* (Fant 1970). In mammals, the *source* of the regular stream of pulses is the glottis in the larynx at the bottom of the throat; the pulse shape is effectively invariant and so the information

Pulse-Resonance Sounds, Fig. 1 The waveform (a) and magnitude spectrum (b) of a short segment of an /a/ vowel. It sounds like the vowel in “paw” as spoken by a child

associated with the stream of pulses is primarily the *glottal-pulse rate* (GPR) (the reciprocal of the period of the wave). The GPR determines the fundamental, F_0 , of the series of spectral harmonics that carry the energy of the sound (the set of vertical green lines in Fig. 1b). The spacing of the harmonics decreases as harmonic number increases because the spectrum is plotted on a logarithmic frequency axis. The frequency unit is octaves relative to 100 Hz, and so, 1 is 200 Hz (the reciprocal of 5 ms). The GPR determines the sequence of pitches we hear when a person sings a song; when GPR and the pitch of the voice increase, F_0 and the entire set of harmonics move, as a unit, to the right along this logarithmic frequency axis.

In mammals, the *filter* is the vocal tract between the larynx and the lips; the vocal cavities of this filter impose resonances on the glottal

pulses which appear as peaks in the magnitude spectrum. Collectively, the resonances impose a shape on the envelope of the frequency spectrum (the blue line in Fig. 1b), and this *envelope shape* is what determines vowel type (/a/, /e/, /i/, /o/, /u/, etc.). In speech research, the peaks in the spectral envelope are referred to as “formants,” and the position of the spectral envelope along the frequency axis is expressed in terms of the geometric mean formant frequency (MFF) (e.g., Assmann and Nearey 2008; Irino et al. 2012).

The Size Information in Pulse-Resonance Sounds

It is a general principle of mechanical vibration that larger/heavier things vibrate more slowly than smaller/lighter things. The sources and the filters

in the bodies of animals developed, evolutionarily, from preexisting body parts. As a result, as an individual matures, the source and the filter increase in size. For example, in mammals, the components of the vocal tract that compose the filter are tubes that connect the openings of the mouth and nose to the lungs and the stomach. These tubes are essential for life and they have to increase in length as the body of an individual matures and the nose and mouth move further and further away from the lungs and stomach. In humans, vocal tract length increases almost linearly with height from age three (Fitch and Giedd 1999; Turner et al. 2009, Fig. 4).

The effects of source size and filter size on the waveform of a vowel are illustrated in Fig. 2. The shape of the resonance is the same in each cycle of all four waves. In the left column, one person has spoken two versions of /a/ using a high (a) and a low (b) GPR; the pulse rate determines the pitch of the voice. The resonances have the same form since it is the same person speaking the same vowel. In the right column, a short person (c) and a tall person (d) have spoken versions of

/a/ on the same pitch. The pulse rate and the shape of the resonance are the same, but the rate at which the resonance proceeds within the glottal cycle is slower in the lower panel. This person has the longer vocal tract and so their resonances ring longer.

In signal processing terms, changes in the size variables cause dilation in the waveform of a pulse-resonance sound. Changes in F0 cause dilation in the period of the pulse stream; changes in MFF cause dilation in the period of the resonance. Note, however, that the two size variables are mathematically independent, within the constraint that the pitch period has to be sufficiently long to permit the resonance to run for a reasonable proportion of its natural duration.

The Role of Size Information in Speaker Perception

The effect of size on the magnitude spectrum of a vowel is illustrated schematically in Fig. 3. The spectrum used to illustrate the /a/ vowel of a child in Fig. 1 is shown in the upper right-hand panel of the figure. The size information appears in the

Pulse-Resonance Sounds, Fig. 2 Left panel: Two /a/ vowels spoken by one person on low and high pitch. Right panel: Two /a/ vowels spoken by different people, one with a short and one with a long vocal tract

Pulse-Resonance Sounds, Fig. 3 Magnitude spectra for an /a/ vowel as spoken by four different people, a child, a man, a male dwarf, and a castrato. The harmonics are

shifted one octave toward the origin in the *left* column; the spectral envelope is shifted one octave toward the origin in the *lower* row

position variables, F0 and GPR. The GPR and MFF are both relatively high in the upper right-hand panel, and it is this combination of GPR and MFF that produces the sound of a child's voice. As a child matures into an adult, the GPR and the MFF both decrease, and the average decrease for males and females is approximately one octave for both MFF and GPR (Lee et al. 1999).

In Fig. 3, the GPR in the panels of the left-hand column is one octave below that in the panels of the right-hand column; the set of harmonics (green) is shifted, as a unit, one octave toward the origin, on this logarithmic frequency scale. Similarly, in the panels of the lower row, the spectral envelope is shifted, as a unit, one octave toward the origin on this logarithmic frequency scale, and the MFF in the lower row is one octave below that in the upper row. The logarithmic frequency scale converts the dilation of the waveform into a frequency shift in the magnitude spectrum. In the lower left-hand panel, the voice has a combination of a relatively low GPR and a relatively low MFF, and this combination of GPR and MFF produces the sound of a man's voice.

Although, the descent of F0 and MFF is highly correlated in normal human development, the two size variables are acoustically independent to a

large degree, and occasionally, the ratio of F0 to MFF can be considerably larger or smaller than normal. The effects are most pronounced in males where a sex-related release of hormones at puberty causes the vocal folds of males to grow and add weight which in turn causes F0 to decrease disproportionately in males. In the nineteenth century, the hormone release was occasionally inhibited artificially in choir boys to prevent the normal pitch break at puberty. As the boy increased in stature and MFF decreased as normal, the voice developed an *unusually large F0-to-MFF ratio* because the F0 did not decrease disproportionately. The situation is illustrated in the lower right-hand panel of Fig. 3, and it explains the distinctive singing voice referred to as a "castrato." Today, counter tenors produce a somewhat similar effect by singing in falsetto voice, that is, they temporarily inflate the F0-to-MFF ratio by artificially increasing their pitch while singing. An *unusually small F0-to-MFF ratio* arises when the hormones that induce normal body growth are not produced in sufficient amounts; growth in stature is restricted and with it the decrease in MFF that accompanies the normal increase in vocal tract length. Nevertheless, the sex-related increase in vocal fold size still occurs and F0 drops by the

normal amount at puberty. This explains the distinctive voice of the dwarf, where the pitch is unusually low for the vocal tract length.

Before the age of puberty, as girls grow in stature, F0 and MFF both decrease but they do so in a way that preserves the F0-to-MFF ratio (Turner et al. 2009, Fig. 13). Near the time of puberty, girls have a growth spurt, but even during this phase, the F0-to-MFF ratio remains effectively the same, with the result that women have almost the same F0-to-MFF ratio as girls (and boys). The ratio is larger than it is for men because F0 is disproportionately low in men. In any event, it is the F0-to-MFF ratio that primarily distinguishes the voices of women and children from the voices of men.

In summary, when a person is speaking, the F0 and MFF are largely responsible for communicating the size of the speaker and, in adults, the ratio of F0 to MFF provides an important cue as to whether the speaker is a man or a woman. The message of the communication is conveyed by the shape of the spectral envelope which is largely independent of the size variables, F0 and MFF.

Background and Research on Pulse-Resonance Sounds

The remainder of this entry provides a little background information on the mathematics underlying pulse-resonance sounds and some recent research projects that it has spawned. The paragraphs are intended to provide the reader with leads they might want to follow up rather than a working knowledge of each topic.

Background Mathematics

About 20 years ago, sections of the signal processing community began to suspect that the traditional time-frequency representation of sound (the spectrogram) was probably not the best representation for automatic speech recognition, and Cohen (1993) suggested an alternative time-scale representation of sound. The mathematics of acoustic scale suggested that it should be possible to construct a scale-invariant representation of

speech sounds. This was important because when a traditional automatic speech recognition (ASR) system is trained on the speech of one person, the system does not generalize well to the speech of people who differ in size. It was argued that if the spectrogram of the traditional ASR system was replaced by a scale-invariant representation of speech, it would facilitate both the learning and recognition stages of ASR. Umesh et al. (1999) illustrated the potential of the time-scale representation for ASR.

The Auditory Representation of Acoustic Scale

The mathematics of acoustic scale prompted Irino and Patterson (1997, 2002, 2006) to revise their computational model of auditory processing and show how the auditory system might construct a scale-invariant representation of pulse-resonance sounds. In their model, the spectral analysis performed by the cochlea is simulated by an auditory *wavelet transform* rather than a windowed Fourier transform. It is referred to as a dynamic, compressive gammachirp filterbank (Irino and Patterson 2006). The frequency/scale dimension of the wavelet transform is quasi-logarithmic which gives the auditory image a normalized scale dimension by default. The initial stages of neural processing are simulated by “strobed” temporal integration (STI) – a process that stabilizes the repeating neural pattern produced in the auditory nerve by successive cycles of a vowel (Patterson 1994). The resulting two-dimensional representation of sound is referred to as an auditory image. The STI calculation is a simplified version of autocorrelation which Licklider (1951) suggested as a neural mechanism for pitch extraction more than 60 years ago. STI has the advantage of preserving the temporal asymmetry of pulse-resonance sounds which means that it can be used to explain aspects of timbre perception that autocorrelation cannot (Patterson and Irino 2013).

Irino and Patterson (2002) showed that the temporal dimension of the auditory image could be normalized by converting the units of the time-like dimension into cycles of the impulse response of the auditory filter (on a channel-by-channel

basis). Mathematically, the processes that generate the auditory image are a form of stabilized, wavelet-Mellin transform (SWMT), and the representation it produces is scale-shift *invariant*. It is, however, somewhat complex and it has not been successfully applied to ASR as yet.

A Scale-Shift Covariant Auditory Image

A more intuitive version of the normalized auditory image that is scale-shift *covariant* has since been developed (Patterson et al. 2007). The auditory image of a synthetic two-formant /a/ vowel is presented in Fig. 4 to illustrate the form and value of scale-shift covariance. The two formants have the same mathematical form (a simple damped resonance), and they simulate the action of the throat and mouth cavities of the vocal tract. The only difference between them is that one cavity is smaller than the other. In the scale-shift covariant auditory image (Fig. 4), the two resonators produce the same pattern of activity and the cavity size information is coded separately as the vertical position of the pattern. The representation is covariant, rather than invariant, because the size information remains in the auditory image. The combined distribution produced by the pair of formants represents the vowel-type information, which in this example is /a/. There are figures showing the form of the vowel information at earlier stages of processing in Patterson et al. (2007). In those representations,

Pulse-Resonance Sounds, Fig. 4 The /a/ vowel of a man as it appears in the scale-shift covariant version of the auditory image

the upper vowel pattern is shorter than the lower vowel pattern and it is somewhat twisted relative to the lower pattern.

When speaker with a different size speaks the same /a/ vowel, the change in vocal tract length causes proportionate changes in vocal cavity length, and the complete vowel-type distribution moves vertically in the auditory image without changing shape – up for a shorter VTL and down for a longer VTL. The blue diagonal shows the period of the vowel which is the pitch information in the auditory image (the transformation from time-like units to cycles causes it to rotate from its vertical orientation in earlier representations). When the size of the speaker changes, the associated change in vocal cord size causes the diagonal to move vertically in the image without changing its angle, and the shift is independent of both the shape and position of the vowel-type distribution. The diagonal also restricts the vowel-type distribution to the part of the space above the diagonal. In the voices of tall women, the diagonal can encroach on the vowel-type distribution and limit the extent of the first formant in the cycles dimension.

Terminology of Acoustic Scale

In the most recent version of the terminology (Patterson et al. 2010), the rate of oscillation of a vocal resonance (or a set of vocal resonances) is referred to as the “acoustic scale of the filter element of the sound” (S_f), and the pulse rate is referred to as the “acoustic scale of the source element of the sound” (S_s) (Patterson and Irino 2013). The values of these acoustic variables describe the size, or scale, of acoustic features in the waveform, and they describe the position of their counterparts in the magnitude spectrum (when plotted on a log-frequency axis).

Research on Pulse-Resonance Sounds

There are two software packages that allow one to manipulate the S_f and S_s of natural speech sounds, so that utterances recorded by a man could be transformed to sound like those of a woman or a child and vice versa; their names are

STRAIGHT (Kawahara et al. 1999) and PRAAT (Boersma 2001). They made it possible to record the speech sounds of one individual and then synthesize populations of speakers with widely varying vocal characteristics who were all speaking the same set of utterances with the same accent and the same prosodic details. These speaker sets were used to perform behavioral experiments on the perception of S_f and S_s separately and in combination.

The Robustness of Speech Perception to Variation in S_f and S_s

The initial experiments were designed to provide quantitative evidence for what everyone intuitively knows, namely, that speech perception is singularly robust to changes in the S_f and S_s values of communication sounds. We have no difficulty whatsoever understanding when a child and an adult have spoken the same speech sounds (vowels, syllables, or words), despite substantial differences in the S_f and S_s values of the sounds. Indeed, we can recognize speech sounds when the S_f and S_s of the voice have been scaled well beyond the range of normal experience and when the combination of S_f and S_s values is not one that occurs in the normal population (Smith et al. 2005; Assmann and Nearey 2008). The recognition performance of humans stands in marked contrast to that of machines; if an ASR system is trained on a man's voice, it is unlikely to work for a woman, let alone a child.

The behavioral experiments with scaled speech sounds also showed that listeners can specify the size and sex of speakers from random samples of their speech sounds (Smith and Patterson 2005). Discrimination experiments were performed with sequences of vowels, syllables, and words to determine the just noticeable difference (JND) for changes in S_f which listener's hear as a change in speaker size. The JND is defined as the change in S_f required to support 76 % correct identification of which of two speakers is the smaller (or larger). The results are surprisingly simple: The JND for S_f was about 8 % with vowel sounds

(Smith et al. 2005), 5 % with syllables (Ives et al. 2005), and 5 % with words (Irino et al. 2012), and these values are roughly the same over a wide region of the $S_f - S_s$ plane, that is, for voices with very different combinations of S_f and S_s . For comparison, the JND for noise level (loudness) is about 10 % and the JND for light level (brightness) is about 15 %. The experiment of Irino et al. (2012) also compared discrimination performance for voiced words with that for whispered words and showed that the JND for whispered words is also 5 % provided the words are clearly audible.

In short, the experiments support the hypothesis that the auditory system automatically normalizes communication sounds for S_f and S_s to segregate the message from the vocal characteristics.

PyNN: A Python API for Neural Network Modelling

Andrew P. Davison

Unité de Neurosciences, Information et Complexité (UNIC), Institut de Neurobiologie Alfred Fessard, Centre National de la Recherche Scientifique (CNRS), Gif-sur-Yvette, France

Definition

PyNN is an application programming interface (API) for describing and simulating neuronal network models in the Python programming language. Numerical solution of the model equations is performed by a “backend” simulator, which as of PyNN version 0.7 can be any of NEURON (Hines and Carnevale 1997), NEST (Gewaltig and Diesmann 2007), Brian (Goodman and Brette 2008), or PCSIM (Pecevski et al. 2009). Alternatively, the backend can be a neuromorphic hardware system (Bruderle et al. 2009; Galluppi et al. 2010). PyNN thus provides a simulator-independent method for describing spiking neuronal network models. Data generated by the backend simulator is reformatted by PyNN into a standard format, and thus PyNN can also be used as a base platform on which to build simulator-independent data analysis and visualization tools.

Detailed Description

The PyNN API allows the construction and simulation of neuronal network models in a simulator-independent way, i.e., the same Python script can be used to perform simulations on any of the supported backend simulators or hardware devices. The results are expected to be quantitatively the same within certain limits determined by the choice of numerical algorithms made by different simulators. PyNN provides a limited number of standardized neuron and synapse models (including synaptic plasticity) that are each available in at least two of the supported

p-Value

► Significance Evaluation

simulators. At the present time, all of the neuron models are point neuron models such as the integrate-and-fire family of models or single-compartment Hodgkin-Huxley models. Multi-compartment models are not yet supported in a simulator-independent way, although they can be used with those simulators that support them. Arbitrary network structure and connectivity may be expressed with the API. PyNN provides a library of commonly used connectivity patterns, but user-defined patterns are straightforward to write.

The implementation of PyNN is made much simpler by the widespread adoption of Python as an interface language for neuronal network simulators (Davison et al. 2009). For each supported backend simulator, the PyNN API is implemented in terms of the native Python API of that simulator. For simulators that do not provide a Python interface, PyNN can generate code in the language used by that simulator. The same approach can be used for other simulator-independent model description languages such as NeuroML (Gleeson et al. 2010).

PyNN is open-source software, developed by an informal community and distributed under the CeCILL license. An automated test suite and continuous integration software are used to verify correct behavior and minimize bugs. The project homepage is at <http://neuralensemble.org/PyNN>. This page contains links to detailed documentation, to the version control repository, and to the bug tracker.

Q

Q Current

► [Hyperpolarization-Activated Cyclic Nucleotide Gated Channels](#)

dependence of maximum channel conductance on temperature.

Detailed Description

Mathematical Definition

The Q_{10} of a process is defined as

$$Q_{10} = \frac{\text{Rate of process at temperature } T + 10^{\circ}\text{C}}{\text{Rate of process at temperature } T}$$

Usage

If the rate r of a process at temperature T is known, the rate at another temperature T_1 can be estimated using

$$r(T_1) = r(T)Q_{10}^{(T_1-T)/10}$$

For example, in a model of an ion channel in the formalism used by Hodgkin and Huxley (1952), the opening and closing rate coefficients of a particular gating particle at temperature T might be $\alpha(T)$ and $\beta(T)$. To scale these to temperature T_1 , the following relations can be used:

$$\begin{aligned}\alpha(T_1) &= \alpha(T)Q_{10}^{(T_1-T)/10} \text{ and } \beta(T_1) \\ &= \beta(T)Q_{10}^{(T_1-T)/10}\end{aligned}\quad (1)$$

Q10: The Effect of Temperature on Ion Channel Kinetics

Synonyms

[Temperature coefficient](#)

Definition

The Q_{10} is a measure of the degree to which a biological process depends on temperature. It is defined as the ratio between the rate of a biological process at two temperatures separated by 10°C . In the context of ion channels, it can be applied to the temperature dependence of the rate of channel opening and closing and to the

If the ion channel kinetics are expressed in terms of the time constant $\tau = 1/(\alpha + \beta)$, the transformation is

$$\tau(T_1) = \tau(T)Q_{10}^{(T_1-T)/10} \quad (2)$$

Measurement and Validity

The Q_{10} can be measured empirically at a particular base temperature T . As described later, the Q_{10} is expected to vary depending on the base temperature used for the measurement. There are more theoretically based ways than the Q_{10} for adjusting for temperature in complex models of ion channels (Sterratt et al. 2011). However, the Q_{10} can be a practical approximation to relate measurements at one temperature to measurements or models at other temperatures.

Typical Values

The rate of opening and closing of ion channels typically has a Q_{10} in the range 2.4–4 (Hille 2001). The maximum conductance of an ion channel varies with temperature with a Q_{10} in the range 1.2–1.5 (Hodgkin et al. 1952; Hille 2001).

Physical Basis

According to the Arrhenius equation, a chemical reaction has an associated activation energy ΔE and the rate $r(T)$ of the reaction at temperature T (in kelvins) is given by

$$r(T) = A \exp\left(-\frac{\Delta E}{k_B T}\right) \quad (3)$$

where k_B is Boltzmann's constant and A is a constant of proportionality. According to the definition of the Q_{10} , this gives

$$Q_{10} = \frac{r(T+10)}{r(T)} \quad (4)$$

$$= \exp\left(-\frac{\Delta E}{k_B(T+10)} + \frac{\Delta E}{k_B T}\right) \quad (5)$$

$$= \exp\left(\frac{\Delta E}{k_B} \left(\frac{10}{T(T+10)}\right)\right) \quad (6)$$

Thus, the Q_{10} is expected to depend on the measurement temperature. However, this dependence is small for the temperature ranges within which ion channels operate. For example, if the Q_{10} of a reaction calculated from rates at 5 °C and 15 °C is found to be 3, the Q_{10} calculated at 27 °C and 37 °C would be 2.57, a reduction of 14%. This can be shown by rearranging Eq. 6 to obtain $\Delta E/k_B$:

$$\frac{\Delta E}{k_B} = \ln Q_{10}^{5-15} \frac{T(T+10)}{10} \quad (7)$$

where $T = 5$ °C is the lower measurement temperature, and then substituting this value of $\Delta E/k_B$ back into Eq. 6 with $T = 27$ °C.

Definition

Quadratization of biophysical (conductance-based) models having a parabolic-like voltage nullcline in the subthreshold voltage regime refers to the process by which these models are substituted by “caricature” models having a strictly parabolic voltage nullcline and a linear nullcline for the recovery variable. We refer to the latter as quadratic or parabolic models. The parabolic-like and strictly parabolic voltage nullclines coincide at their extrema (minima or maxima) and are well approximated by each other in vicinities of these extrema whose sizes depend on the model parameters. Quadratic models are simplified by a change of variables that translates these extrema to the origin of the phase-plane diagram. A further simplification (parameter reduction) can be achieved by nondimensionalizing the quadratic models. This procedure can be extended to three-dimensional models having a parabolic-cylinder-like shaped voltage nullsurface and to models having time-dependent inputs and synaptic currents.

Detailed Description

Introduction

Reduced models of neuronal activity often involve a detailed description of the subthreshold

dynamics supplemented with artificial spikes (Izhikevich 2006; Ermentrout and Terman 2010; Borgers 2017). One classification of the different types of mathematical descriptions of the neuronal subthreshold dynamics consists of two groups: biophysical and phenomenological. Biophysical models include the description of the interplay of the ionic currents that operate in the subthreshold voltage regime in terms of electric circuit parameters such as capacitances, conductances, and reversal potentials, among others. These models can be thought of as conductance-based models of Hodgkin-Huxley (HH) type (Hodgkin and Huxley 1952) where the spiking currents (transient sodium and delayed-rectifier potassium) have been removed (Lapicque 1907; Ermentrout and Terman 2010; Gerstner et al. 2014; Rotstein et al. 2006; Smith et al. 2000; Izhikevich 2006). Phenomenological models, on the other hand, consist of heuristic dynamic equations that include idealized versions of the types of nonlinearities (e.g., parabolic, cubic) and time constants that are assumed to be present in the system. The parameters have no explicit connection to the neuronal biophysics, but these models can be used to understand the neuronal dynamic mechanisms in terms of relatively simple sets of equations and the geometry of the phase-plane diagrams. In both types of models, the parameters can be fitted to match the observed experimental patterns. However, the results of using phenomenological models lack a biophysical interpretation in the absence of an explicit link to the biophysical models.

In the so-called leaky integrate-and-fire (IF) model, the subthreshold dynamics are linear and one-dimensional. The quadratic and exponential IF models have also one-dimensional subthreshold dynamics and include the said type of nonlinearities for the evolution of the equation for V (Latham et al. 2000; Hansel and Mato 2001; Fourcaud-Trocme et al. 2003). Models with two-dimensional dynamics can be obtained by adding a recovery variable (w) with linear dynamics to the models mentioned above, giving rise to the linear resonate-and-fire models (Izhikevich 2001) and the nonlinear adaptive quadratic (Izhikevich 2003) and exponential (Brette and Gerstner 2005)

IF models. More complex models with three-dimensional subthreshold dynamics that include two recovery variables mimicking ionic currents with slow dynamics have been used to a lesser extent (e.g., hyperpolarization-activated mixed sodium-potassium, T-type calcium, adaptive) (Rotstein et al. 2006; Smith et al. 2000).

Phenomenological models of quadratic IF type with strictly parabolic V -nullclines in the subthreshold regime (Izhikevich 2003) have been frequently used as ad-hoc models to investigate the dynamics of neurons in a variety of systems. The lack of an explicit connection with the neuronal biophysics limits the scope of these studies as well as network studies that combine the two modeling approaches (phenomenological and biophysical) for different neuron types in the same circuits (Tikidji-Hamburyan et al. 2015; David et al. 2015). For example, phenomenological models cannot capture the effects of changes in the biophysical conditions (e.g., ionic currents levels, synaptic connectivity) on the resulting patterns. These models also fail to capture the existence of patterns with equal attribute values (e.g., firing frequency) generated by neurons with different biophysical properties (Prinz et al. 2004; Rotstein et al. 2016) or the effects of these types of heterogeneous neurons on the network patterns in which they are embedded. These issues are not unique for models of adaptive quadratic IF models, but they are shared by all phenomenological models. Linearization of conductance-based models (Richardson et al. 2003; Koch 1999) provides explicit formulas for the parameters in the linearized models in terms of the biophysical parameters (Izhikevich 2001; Rotstein 2013, 2014a), but linear models fail to capture important dynamic effects (Rotstein 2015).

In this entry, we present a systematic reduction of biophysical (conductance-based) models with parabolic-like V -nullclines (nullsurfaces) to phenomenological models with strictly parabolic V -nullclines (nullsurfaces) and linear nullclines (nullsurfaces) for the recovery variable(s). We refer to these reduced models as parabolic or quadratic and to the reduction process as

quadratization. The approach presented here extends the concept of linearization to include second order derivatives in voltage and captures the quadratic nonlinearities in close vicinities of the extrema of the parabolic-like nullclines for the underlying two-dimensional system. It is different from the approach discussed in Izhikevich (2006) where a phenomenological quadratic model is presented ad hoc and no explicit formulas that link its parameters with the biophysical parameters are provided. Although the phenomenological parameters can be approximated by using the steady-state $I - V$ relation, this needs to be measured experimentally or computed numerically. Our approach allows for a biophysical straightforward biophysical interpretation of the results using the quadratic model.

We focus on two- and three-dimensional models having one or two voltage-dependent gating variables, respectively (each of which correspond to an ionic current) and an additional gating variable with fast dynamics (slave to voltage). The system consisting of the voltage equation together with an equation for one of the gating variables (x_1) is thought to be the “main” system. The second gating variable (x_2), typically slower, is considered to have a modulatory effect in the sense that the projections of the V -nullsurface onto planes parallel to the V - x_1 plane remain parabolic-like in the subthreshold regime. We also include a time-dependent input current and a synaptic current in order to make the reduction amenable for network models, although we do not discuss these models here.

After an appropriate translation, the minimum of the strictly parabolic V -nullcline is located at the origin of the phase-plane diagram. The strictly parabolic V -nullcline is concave up. If the parabolic-like V -nullcline is concave-down, then the quadratization process includes an inversion of the V -nullcline. An additional simplification (nondimensionalization) reduces the number of parameters further, but it changes the definitions of the time and the dependent variables. Importantly, the units of the variables in the quadratic model are different from their original units. This approach produces formulas that relate the parameters of the quadratic model with the biophysical

parameters. This is necessary for the biophysical interpretation of the results using caricature models.

The quadratization procedure described in this entry assumes that the V -nullcline (nullsurface) is parabolic-like (parabolic-cylinder-like shaped) in the subthreshold voltage regime. This is often overlooked when phenomenological models of quadratic IF type with strictly parabolic V -nullclines are used. In fact, the neuronal subthreshold dynamics are often governed by other types of nonlinearities such as cubic-like ones (Rotstein 2017, 2014b; Remme et al. 2012). Whether the subthreshold dynamics have parabolic- or cubic-like nonlinearities may not be apparent from the identity of the participating ionic currents in the biophysical models (Izhikevich 2006; Rotstein 2017). As shown in previous work, models with the same combination of ionic currents may give rise to different types of nonlinearities (parabolic- and cubic-like) in the subthreshold regime (Rotstein 2017).

We discuss additional limitations of the quadratization procedure and the use of quadratic models later in this entry.

Models

Conductance-Based Models

We use conductance-based models of Hodgkin-Huxley type (Hodgkin and Huxley 1952) to describe the neuronal subthreshold dynamics. Our formulation allows for various combinations of ionic currents that have been shown to underlie the generation of subthreshold resonance, including persistent sodium (I_{Nap}), h- (I_h) and slow potassium currents (I_{Ks}) (Acker et al. 2003; Schreiber et al. 2004; Rotstein et al. 2006; Izhikevich 2006) (see below). However, we do not include the spiking currents (transient sodium and delayed-rectifier potassium). The onset of spikes is described by the models we use. In order to describe the spiking dynamics either these currents have to be included or spikes have to be added manually after their onset.

For generality, in our description we use non-specific ionic currents. We discuss specific model

examples later in this section. The current-balance equation is given by

$$C \frac{dV}{dt} = I_L - I_1 - I_2 - I_3 + I_{app} + A_{in} I(t) - I_{syn}, \quad (1)$$

where V is the membrane potential (mV), t is time (msec), C is the membrane capacitance ($\mu(\text{farad})/\text{cm}^2$), I_{app} is the applied bias (DC) current ($\mu(\text{ampere})/\text{cm}^2$), $I(t)$ is a time-dependent input current with amplitude A_{in} ($\mu\text{A}/\text{cm}^2$), $I_L = G_L (V - E_L)$ is the leak current, I_j ($j = 1, 2, 3$) are ionic currents, and I_{syn} is a synaptic current. The ionic currents we consider here are of the form

$$I_j = G_j x_j (V - E_j) \quad (2)$$

where x_j are the gating variables, G_j the maximal conductances (mS/cm^2), and E_j the reversal potentials (mV).

All gating variables x obey a first order differential equation of the form

$$\frac{dx}{dt} = \frac{x_\infty(V) - x}{\tau_x(V)} \quad (3)$$

where $x_\infty(V)$ and $\tau_x(V)$ are the voltage-dependent activation/inactivation curves and time-scales, respectively.

The synaptic current we consider has the form.

$$I_{syn} = G_s s(t) (V - E_s) \quad (4)$$

where $s(t)$ is the synaptic function, G_s the maximal synaptic conductance, and E_s the synaptic reversal potential.

The ionic currents we consider here (Eq. 2) are restricted to have a single gating variable x and to be linear in x . In addition, in this entry we focus on two-dimensional models having two dynamic gating variables (x_1 and x_2) and an additional gating variable evolving on a fast time scale for which the adiabatic approximation $x_3 = x_{3,\infty}(V)$ is justified. Additional fast currents can be included without significantly changing the formalism.

Models of Quadratic Type

The models of quadratic type we use in this entry have the form

$$\frac{dv}{dt} = \sigma av^2 - w + \hat{A}_{in} I(t) - g_s s(t) (v - \hat{E}_s) \quad (5)$$

$$\frac{dw}{dt} = \epsilon [\alpha v - w - z], \quad (6)$$

$$\frac{dz}{dt} = \epsilon \eta [-\gamma v - z + \lambda]. \quad (7)$$

For two-dimensional biophysical models, the geometric model reduces to Eqs. 5 and 6 with z substituted by λ .

$$\frac{dv}{dt} = \sigma av^2 - w + \hat{A}_{in} I(t) - g_s s(t) (v - \hat{E}_s), \quad (8)$$

$$\frac{dw}{dt} = \epsilon [\alpha v - w - \lambda]. \quad (9)$$

Collectively, we refer to the parameters $a, \alpha, \gamma, \lambda$, and σ as the geometric parameters since they control the geometry of the phase-space diagram: α and γ control the slope of the w and z nullsurfaces, respectively, λ controls the relative displacement between the v - and the z nullsurfaces (or between the v - and w nullclines in the two-dimensional case). The parameter a is assumed to be positive. The product σ controls the curvature of the parabolic V -nullcline. The concavity sign is captured by $\sigma = \pm 1$. By an appropriate change of variables when $\sigma = -1$ (concave down parabolic v -nullcline), the model can be transformed into one having a concave up parabolic v -nullcline.

The dynamic parameters ϵ and η represent the time scale separation between the variables v and w_1 , and between the variables w_1 and w_2 , respectively. For simplicity we assume that $\eta < 1$.

The geometric and dynamic parameters and the parameters $\hat{A}_{in}$, g_s , and $\hat{E}_s$ can be expressed in terms of the biophysical parameters in Eqs. 1, 2, 3, and 4. We provide these expressions below and

briefly explain the quadratization procedure that brings the biophysical model (1), (2), (3), and (4) into the quadratic model (5), (6), and (7).

The units of the variables and parameters in Eqs. 5, 6, and 7 are $[v] = \text{mV}$, $[w] = \text{mV/msec}$, $[z] = \text{mV/msec}$, $[\epsilon] = 1/\text{msec}$, $[\eta] = 1$, $[a] = 1/(\text{msec mV})$, $[\alpha] = 1/\text{msec}$, $[\gamma] = 1/\text{msec}$, $[\lambda] = \text{mV/msec}$, $[\hat{A}_{in}] = \text{mV/msec}$, $[g_s] = 1/\text{msec}$, and $[\hat{E}_s] = \text{mV}$. Some of these variables and parameters involve the capacitance C . When it is assumed to be $C = 1$ and not included in the definitions of the variables and parameters, $[w] = \text{mS mV/cm}^2$, $[z] = \text{mS mV/cm}^2$, $[a] = \text{mS}/(\text{cm}^2 \text{mV})$, $[\alpha] = \text{mS}/\text{cm}^2$, $[\gamma] = \text{mS}/\text{cm}^2$, $[\lambda] = \text{mS mV/cm}^2$, $[\hat{A}_{in}] = \mu\text{A}/\text{cm}^2$, and $[g_s] = \text{mS}/\text{cm}^2$.

Dimensionless Models of Quadratic Type

System (5), (6), and (7) can be put in dimensionless form with the consequent reduction in the number of parameters

$$\frac{d\bar{v}}{d\bar{t}} = \sigma \bar{v}^2 - \bar{w} + \bar{A}_{in} I(\alpha^{-1} \bar{t}) - \bar{g}_s s(\alpha^{-1} \bar{t}) (\bar{v} - \bar{E}_s) \quad (10)$$

$$\frac{d\bar{w}}{d\bar{t}} = \bar{\epsilon} [\bar{\alpha} \bar{v} - \bar{w} - \bar{z}], \quad (11)$$

$$\frac{d\bar{z}}{d\bar{t}} = \bar{\epsilon} \eta [-\bar{\gamma} \bar{v} - \bar{z} + \bar{\lambda}], \quad (12)$$

by a nondimensionalization process, where

$$\bar{t} = \alpha t, \quad \bar{v} = \frac{a}{\alpha} v, \quad \bar{w} = \frac{a}{\alpha^2} w, \quad \bar{z} = \frac{a}{\alpha^2} z, \quad (13)$$

$$\bar{\epsilon} = \frac{\epsilon}{\alpha}, \quad \bar{\gamma} = \frac{\gamma}{\alpha}, \quad \bar{\lambda} = \frac{\lambda a}{\alpha^2}, \quad (14)$$

$$\bar{A}_{in} = \frac{\hat{A}_{in} a}{\alpha^2}, \quad \bar{g}_s = \frac{g_s}{\alpha}, \quad \bar{E}_s = \frac{\hat{E}_s a}{\alpha}. \quad (15)$$

Quadratization Procedure

We assume that $\tau_1 < \tau_2$ (x_2 is slower than x_1). We also assume that the projection of the

V -nullsurface onto the planes parallel to the V - x_1 plane (constant values of x_2) are parabolic-like functions. In other words, we assume that the presence of the variable x_2 does not qualitatively change the shape of the parabolic-like V -nullcline of the two-dimensional system (for $x_2 = 0$), but it can only produce parabolic-like deformations, raise it and shift it down as in Rotstein et al. (2006). The case $\tau_2 = \tau_1$ is excluded because the system can be reduced to a quasi-two-dimensional (Rotstein 2017).

As a starting point, we identify the minimum ($V_{min}, x_{1,min}, 0$) or maximum ($V_{max}, x_{1,max}, 0$) of the parabolic-like V -nullcline (for $x_2 = 0$). We refer to them indistinctly as $(V_e, x_{1,e}, x_{2,e})$. We define

$$\begin{aligned} u &= V - V_e, \\ w &= \frac{x_1 - x_{1,e}}{x'_{1,\infty}(V_e)}, \\ w_2 &= \frac{x_2 - x_{2,e}}{x'_{2,\infty}(V_e)}. \end{aligned} \quad (16)$$

We then expand the right-hand sides of Eqs. 1 and 3 around $(V_e, x_{1,e}, x_{2,e})$ up to the first order in x_1 and x_2 and up to the second order in V . This yields

$$\begin{aligned} C \frac{du}{dt} &= F_e - g_L u + \sigma g_c u^2 - g_1 w_1 \\ &\quad - g_2 w_2 + A_{in} I(t) \\ &\quad - G_s s(t) (u + V_e - E_s) \end{aligned} \quad (17)$$

and

$$\bar{\tau}_j \frac{dw_j}{dt} = (1 - \xi_j)u - w_j + \beta_j, \quad j = 1, 2, \quad (18)$$

where

$$\begin{aligned} F(V, x_1, x_2) &= I_{app} - G_L(V - E_L) \\ &\quad - G_1 x_1(V - E_1) \\ &\quad - G_2 x_2(V - E_2) \\ &\quad - G_3 x_{3,\infty}(V) (V - E_3), \end{aligned} \quad (19)$$

$$F_e = F(V_e, x_{1,e}, x_{2,e}), \quad (20)$$

$$g_L = G_L + G_1 x_{1,e} + G_2 x_{2,e} + G_3 x_{3,\infty}(V_e) + g_3, \quad (21)$$

$$g_j = G_j(V_e - E_j)x'_{j,\infty}(V_e), \quad j = 1, 2, 3 \quad (22)$$

$$\begin{aligned} \sigma g_c &= \frac{1}{2} \frac{\partial^2 F}{\partial V^2} \\ &= - \frac{G_3 x''_{3,\infty}(V_e) (V_e - E_3) + 2G_3 x'_{3,\infty}(V_e)}{2} \end{aligned} \quad (23)$$

and

$$\begin{aligned} \beta_j &= \frac{x_{j,\infty}(V_e) - x_{j,e}}{x'_{j,\infty}(V_e)} \quad \xi_j = \beta_j \frac{\tau'_j(V_e)}{\tau_j(V_e)}, \\ \bar{\tau}_j &= \tau_j(V_e), \quad j = 1, 2. \end{aligned} \quad (24)$$

In Eq. 23 $g_c > 0$ and the concavity of the original V -nullcline is captured by the sign of $\sigma = \pm 1$. Next, we define

$$v = u - \frac{g_L}{2\sigma g_c}. \quad (25)$$

Substituting into Eqs. 17 and 18 yields

$$\begin{aligned} C \frac{dv}{dt} &= F_e - \frac{g_L^2}{4\sigma g_c} + \sigma g_c v^2 - g_1 w_1 \\ &\quad - g_2 w_2 + A_{in} I(t) \\ &\quad - G_s s(t) \left[v + V_e + \frac{g_L}{2\sigma g_c} - E_s \right], \end{aligned} \quad (26)$$

$$\begin{aligned} \bar{\tau}_j \frac{dw_j}{dt} &= (1 - \xi_j)v \\ &\quad + \beta_j + (1 - \xi_j) \frac{g_L}{2\sigma g_c} - w_j, \\ j &= 1, 2. \end{aligned} \quad (27)$$

Subsequently, we define

$$w = \frac{g_1}{C} w_1 + \frac{g_2}{C} w_2 - \frac{F_e}{C} + \frac{g_L^2}{4\sigma g_c C}. \quad (28)$$

Substituting into Eqs. 26 and 27 we obtain

$$\begin{aligned} \frac{dv}{dt} = & \sigma av^2 - w + \hat{A}_{in} I(t) \\ & - g_s s(t) \left(v - \hat{E}_s \right), \end{aligned} \quad (29)$$

$$\frac{dw_1}{dt} = \epsilon \left[\beta_1 + (1 - \xi_1) \frac{g_L}{2\sigma g_c} + (1 - \xi_1)v - w_1 \right], \quad (30)$$

$$\frac{dw_2}{dt} = \epsilon \eta \left[\beta_2 + (1 - \xi_2) \frac{g_L}{2\sigma g_c} + (1 - \xi_2)v - w_2 \right], \quad (31)$$

where

$$\hat{A}_{in} = \frac{A_{in}}{C}, \quad g_s = \frac{G_s}{C}, \quad \hat{E}_s = E_s - V_e - \frac{g_L}{2\sigma g_c}, \quad (32)$$

$$\epsilon = \frac{1}{\tau_1}, \quad \eta = \frac{\hat{\tau}_1}{\hat{\tau}_2}, \quad a = \frac{g_c}{C}. \quad (33)$$

By differentiating both sides of Eq. 28 with respect to t , substituting Eqs. 30 and 31 and rearranging terms we obtain Eq. 6 where

$$\alpha = \frac{g_1(1 - \xi_1) + g_2\eta(1 - \xi_2)}{C} \quad (34)$$

and

$$\begin{aligned} z = & -\frac{g_2(1 - \eta)}{C} w_2 + \frac{F_e}{C} - \frac{g_L^2}{4\sigma g_c C} \\ & - \frac{g_1\beta_1 + g_2\eta\beta_2}{C} \\ & - \frac{g_1(1 - \xi_1) + g_2\eta(1 - \xi_2)}{2\sigma g_c C} g_L. \end{aligned} \quad (35)$$

By differentiating both sides of Eq. 35 with respect to t , substituting Eq. 31 and rearranging terms we obtain Eq. 7 where

$$\gamma = \frac{g_2(1 - \eta)(1 - \xi_2)}{C}, \quad (36)$$

and

$$\begin{aligned} \lambda = & -\frac{g_2(1 - \eta)}{C} \left[\beta_2 + (1 - \xi_2) \frac{g_L}{2\sigma g_c} \right] \\ & + \frac{F_e}{C} - \frac{g_L^2}{4\sigma g_c C} - \frac{g_1\beta_1 + g_2\eta\beta_2}{C} \\ & - \frac{g_1(1 - \xi_1) + g_2\eta(1 - \xi_2)}{2\sigma g_c C} g_L. \end{aligned} \quad (37)$$

For $g_2 = 0$, substituting into Eqs. 35, 36, and 37 yields $\gamma = 0$ and $z = \lambda$.

Two Examples: $I_{Nap} + I_h$ and $I_{Nap} + I_{Ks}$ Models

We present two two-dimensional and autonomous ($G_2 = G_s = A_{in} = 0$ and $g_2 = g_s = \hat{A}_{in} = 0$) examples: the $I_{Nap} + I_h$ and $I_{Nap} + I_{Ks}$ models (Rotstein 2017, 2015) adapted from Acker et al. (2003) and Rotstein et al. (2006).

The $I_{Nap} + I_h$ involves the interaction between a persistent sodium ($I_{Nap} = I_3$) and a hyperpolarization-activated (or h-) ($I_h = I_1$) currents, where $I_{Nap} = G_p p_\infty(V) (V - E_{Na})$ and $I_h = G_h r(V - E_h)$. The $I_{Nap} + I_{Ks}$ model involves the interaction between a persistent sodium ($I_{Nap} = I_3$) and slow potassium ($I_{Ks} = I_1$) currents, where $I_{Nap} = G_p p_\infty(V) (V - E_{Na})$ and $I_{Ks} = G_q q(V - E_k)$. We use the same I_{Nap} in both models. The activation and inactivation curves we used are given by the following functions (see Fig. 1)

$$p_\infty(V) = 1 / \left(1 + e^{-(V+38)/6.5} \right), \quad (38)$$

$$r_\infty(V) = 1 / \left(1 + e^{(V+79.2)/9.78} \right), \quad (39)$$

$$q_\infty(V) = 1 / \left(1 + e^{-(V+40)/5.5} \right). \quad (40)$$

We used the following time constants $\tau_i(V) = \tau_q(V) = 80$. The nullclines for both models are shown in Fig. 2.

Fig. 3 shows the quadratic approximations for both models in neighborhoods of the knee of the corresponding V -nullclines (subthreshold regime) and the linearization of the corresponding

x_1 -nullclines (r - and q -nullclines, respectively). In Fig. 4, we illustrate that the biophysical and quadratic approximations are in good agreement by comparing the results of using the $I_{Nap} + I_h$ model.

Other Related Quadratic Model Formulations

The subthreshold dynamics in the model proposed in Izhikevich (2006) (see also (Izhikevich 2003, 2010)) is given by

Quadratzation: From Conductance-Based Models to Caricature Models with Parabolic Nonlinearities, Fig. 1 Activation/inactivation curves for the $I_{Nap} + I_h$ and $I_{Nap} + I_{Ks}$ models. The function $p_\infty(V)$, $r_\infty(V)$, and $q_\infty(V)$ are given by Eqs. 38, 39, and 40

Quadratzation: From Conductance-Based Models to Caricature Models with Parabolic Nonlinearities, Fig. 2 Phase-plane diagram for the 2D biophysical $I_{Nap} + I_h$ and $I_{Nap} + I_{Ks}$ models. (a) $I_{Nap} + I_h$ model. (b) $I_{Nap} + I_{Ks}$ model. The activation and inactivation curves are as in

$$C \frac{dv}{dt} = k(v - v_r)(v - v_t) - u + I_{app}, \quad (41)$$

$$\frac{du}{dt} = \epsilon [b(v - v_r) - u], \quad (42)$$

where v is the membrane potential, u is the recovery variable, and the parameters v_r and v_t are the resting membrane potential and the instantaneous threshold potential, respectively.

Equations 41 and 42 can be transformed to Eqs. 8 and 9 with $\hat{A}_{in} = g_s = 0$ by defining the new variables

$$\hat{v} = v - \frac{v_r + v_t}{2} \quad (43)$$

and

$$w = \frac{1}{C} \left[u - I_{app} - k v_r v_t + \frac{k}{4} (v_r + v_t)^2 \right], \quad (44)$$

substituting into Eqs. 41 and 42, rearranging terms, dropping the “hat” sign from $\hat{v}$ and calling

$$a = \frac{k}{C}, \quad \alpha = \frac{b}{C}, \quad (45)$$

and

Fig. 1. We used the following parameter values (a): $C = 1$, $G_L = 0.5$, $G_h = 1.5$, $G_p = 0.5$, $E_L = -65$, $E_{Na} = 55$, $E_h = -20$, $I_{app} = -2.5$. (b): $C = 1$, $G_L = 0.1$, $G_q = 1$, $E_L = -54$, $E_{Na} = 55$, $E_K = -90$, $I_{app} = -0.6$

Quadratization: From Conductance-Based Models to Caricature Models with Parabolic Nonlinearities, Fig. 3 Superimposed phase-plane diagram for the 2D biophysical and parabolic (quadratized) $I_{Nap} + I_h$ and $I_{Nap} + I_{Ks}$ models. (a) $I_{Nap} + I_h$ model. (b) $I_{Nap} + I_{Ks}$

model. The *solid and dashed curves* are the nullclines for the biophysical (as in Fig. 2) and parabolic (quadratized) models, respectively. We used the same parameter values as in Fig. 2

Quadratization: From Conductance-Based Models to Caricature Models with Parabolic Nonlinearities, Fig. 4 Comparison between the voltage time courses for the biophysical $I_{Nap} + I_h$ model and the quadratic approximation, respectively, in the presence of additive white noise. We used the same parameter values as in Fig. 3a (and Fig. 2a). (a) Graph of $V(t)$ for the biophysical model. The *dashed-red line* represents the stable fixed-point V . The difference between the average value of V and V is $\langle V - \bar{V} \rangle =$

$\langle V - \bar{V} \rangle \sim 0.029$ and the variance is $\text{Var}(V) \sim 0.1762$. (b) Graph of $v(t)$ for the quadratic model. The *dashed-red line* represents the stable fixed-point v . The difference between the average value of V and V is $\langle v - \bar{v} \rangle \sim 0.02$ and the variance is $\text{Var}(v) \sim 0.1857$. (c) Graph of the error $E(t)$, defined as $E(t) = (V(t) - \bar{V}) - (v(t) - \bar{v})$. $\langle E \rangle \sim -1.3 \times 10^{-13}$ and $\text{Var}(E) \sim 0.0012$. The statistics for $V(t)$, $v(t)$, and $E(t)$ have been computed over a time interval of 10 s

$$\lambda = \frac{1}{C} \times \left[I_{app} + k v_r v_t - \frac{k}{4} (v_r + v_t)^2 - b \frac{v_t - v_r}{2} \right] \quad (46)$$

This transformation allows to interpret the parameters in Eqs. 41 and 42 in terms of the biophysical parameters.

Limitations and Additional Comments

The quadratic models (5), (6), and (7) and (10), (11), and (12) provide a good approximation to the original biophysical models (1) and (2) for a range of voltage values close enough to the knee of the V -nullcline. The parabolic-like and strictly parabolic V -nullclines (for $x_2 = 0$) coincide at their extrema (minima or maxima) and are well approximated by each other in vicinities of these extrema whose sizes depend on the model parameters. This requires the fixed-point to be close to the extremum (minimum or maximum) of the parabolic-like V -nullcline. Away from these ranges of values of V , but still within the subthreshold voltage regime, there may be significant differences between the parabolic-like and strictly parabolic nullclines. We emphasize the need to check the validity of the use of quadratic models in these regions where the approximations are no longer mathematically valid. One possible solution is to include higher order terms in the expansion of the right-hand side of Eq. 1. However, this increases the complexity of the process given the need to include mixed derivatives. While in some cases the differences between the quadratic model approximation and the original biophysical models may be negligible, in other cases it may be qualitatively important. For example, two-dimensional quadratic models cannot exhibit supercritical Hopf bifurcations (Touboul 2008; Krupa and Szmolyan 2001) nor the associated supercritical canard phenomenon (Krupa and Szmolyan

2001) that requires cubic nonlinearities (Rotstein et al. 2012).

In the quadratic models, the recovery variable nullclines (nullsurfaces) are linear. This may create dynamic differences between the biophysical and phenomenological models. For example, the linear and parabolic nullclines may intersect twice in the subthreshold regime, while the original nullclines do not. This is more likely to happen in models with concave-up parabolic-like nullclines (e.g., Fig. 3b) than in models with concave-down parabolic-like nullclines (e.g., Fig. 3a). As before, one possible solution is to include second order terms in the expansion of the right-hand side of Eq. 3.

When the fixed-point of the biophysical model is not close enough to the extremum of the V -nullcline, the biophysical model is quasi-linear in the subthreshold regime. However, the parabolic-like nonlinearities may still play a role in the global subthreshold dynamics and should not be disregarded. One possible approach in these cases is to linearize Eq. 3 around the fixed-point and not around the extremum of the parabolic-like V -nullcline.

The use of the dimensionless model (10), (11), and (12) involves the rescaling of t and v in addition to the other variables. This makes the comparison among results for different parameter values more difficult and less straightforward, since both v and t may be used in the computation of some attributes. This is particularly important when one investigates the response of neurons to external inputs or network effects. In the latter case, it is important to take into account that the synaptic effective synaptic decay times of excitation and inhibition are affected by the rescaling parameters.

Quasi-active Approximation of Nonlinear Dendritic Cables

Michiel W. H. Remme

Humboldt-Universität zu Berlin, Berlin, Germany

Definition

The quasi-active approximation of a dendritic cable is a linearized description of a cable with voltage-dependent membrane conductances. It is an extension of classical passive cable theory relying on linearization of the voltage-dependent conductances around a reference membrane potential (typically the resting potential). The current thereby acquires a linear current–voltage relationship but still has an activation time constant associated with it that determines its gating dynamics. This approximation accurately describes the frequency-dependent filtering of the nonlinear cable for sufficiently small voltage deflections around the reference potential.

Detailed Description

The use of linearized descriptions of voltage-dependent membrane conductances in *point neuron* models has a rich history, e.g., Hodgkin and Huxley (1952) already used this to analyze the subthreshold (oscillatory) response of the *space-clamped* squid giant axon. However, the first use of such methods in a (not space-clamped) cable dates back to Sabah and Leibovic (1969), also to analyze subthreshold responses of the squid giant axon. The study by Koch (1984) is the first to apply the linearized description specifically to dendrites and study how membrane currents affect dendritic input filtering. Koch introduced the term *quasi-active* cable in this work, and while he used this term to denote only dendritic cables that show band-pass filtering, the term has since been used (as we do here) more generally for any linearized cable that retains the dynamics of voltage-

dependent membrane currents, independent of whether this leads to band-pass or low-pass filtering.

Derivation of the Quasi-active Description of a Nonlinear Dendritic Cable

We consider an infinite dendritic cable with a single voltage-dependent conductance. Let $V(x, t)$ denote the membrane potential (in mV) along the cable at position x (in cm) and time t (in s). The passive properties of the cable are determined by membrane time constant τ (in s) and space constant λ (in cm). The cable expresses a voltage-dependent conductance with a single gating variable $w(x, t)$, which has activation function $w_\infty(V)$ and time constant $\tau_w(V)$ (in s). The equations governing $V(x, t)$ and $w(x, t)$ are

$$\begin{aligned} \tau \frac{\partial V(x, t)}{\partial t} &= \lambda^2 \frac{\partial^2 V(x, t)}{\partial x^2} - (V(x, t) - E_L) \\ &\quad - \frac{\bar{g}_w}{g_L} w(x, t) (V(x, t) - E_w) \\ \tau_w(V(x, t)) \frac{dw(x, t)}{dt} &= w_\infty(V(x, t)) - w(x, t) \end{aligned} \quad (1)$$

with leak conductance g_L (in S/cm²), leak reversal potential E_L , peak conductance of the active current $\bar{g}_w$ (in S/cm²), and reversal potential of the active current E_w .

To obtain the quasi-active approximation of the nonlinear cable, Eq. 1 is linearized about membrane potential V_R . We define the variables $U(x, t) \equiv V(x, t) - V_R$ and $m(x, t) \equiv (w(x, t) - w_\infty(V_R)) / \frac{d}{dV} w_\infty(V_R)$ and employ a Taylor series expansion of Eq. 1. After dropping the higher-order terms, we obtain the linear equations describing the quasi-active cable:

$$\begin{aligned} \hat{\tau} \frac{\partial U(x, t)}{\partial t} &= \hat{\lambda}^2 \frac{\partial^2 U(x, t)}{\partial x^2} - U(x, t) + \phi m(x, t) \\ \tau_w \frac{dm(x, t)}{dt} &= U(x, t) - m(x, t) \end{aligned} \quad (2)$$

where the membrane time constant and space constant are both corrected to include the contribution of the active conductance: $\hat{\tau} = \tau / \left(1 + \frac{g_w}{g_l} w_\infty(V_R)\right)$ and $\hat{\lambda} = \lambda / \sqrt{1 + \frac{g_w}{g_l} w_\infty(V_R)}$ and where $\tau_w = \tau_w(V_R)$ and

$$\phi = \frac{\bar{g}_w(E_w - V_R) \frac{dw_\infty(V_R)}{dV}}{g_l + \bar{g}_w w_\infty(V_R)} \quad (3)$$

The dimensionless parameter ϕ is central in characterizing the effect of the active membrane current and denotes the strength of the feedback that the current provides. Its sign defines whether the current functions as a positive or a negative feedback (or is passive when $\phi = 0$). The system is unstable when a regenerative current is too strong ($\phi > 1$).

Note that many studies use an alternative formulation of these equations and describe the effect of the linearized active current as a phenomenological inductance (or capacitance):

$$\begin{aligned} \hat{\tau} \frac{\partial U(x,t)}{\partial t} &= \hat{\lambda}^2 \frac{\partial^2 U(x,t)}{\partial x^2} - U(x,t) - \frac{I_w(t)}{g_l + \bar{g}_w w_\infty(V_R)} \\ L_w \frac{dI_w(x,t)}{dt} &= U(x,t) - r_w I_w(x,t) \end{aligned} \quad (4)$$

with active membrane current I_w (in mA/cm²), inductance $L_w = r_w \tau_w$ (in H cm²), and resistance $r_w = [\bar{g}_w(V_R - E_w) \frac{d}{dV} w_\infty(V_R)]^{-1}$ (in ohm cm²).

Use of the Quasi-active Cable Description

Impulse Response Function

Since the quasi-active description of a cable is linear, we can determine its response to an arbitrary external input using the cable's impulse response function or Green's function. This function can be obtained by first writing the Fourier transform of Eq. 2:

$$\frac{d^2 \tilde{U}(x, \omega)}{dx^2} = \frac{b^2(\omega)}{\hat{\lambda}^2} \tilde{U}(x, \omega) \quad (5)$$

where $\tilde{U}(x, \omega)$ is the Fourier transform of $U(x, t)$ with respect to time, $\omega = 2\pi f$ with frequency f (in Hz), and

$$b(\omega) = \sqrt{1 - \frac{\phi}{1 + \omega^2 \tau_w^2} + i\omega \left(\hat{\tau} + \frac{\phi \tau_w}{1 + \omega^2 \tau_w^2} \right)} \quad (6)$$

Note that the fraction $\frac{b^2(\omega)}{\hat{\lambda}^2}$ in Eq. 5 is also referred to as the propagation constant $\gamma^2(\omega)$. Solving the second-order ODE Eq. 5 when a δ -current impulse is injected at the origin of the infinite cable gives the Fourier transform of the impulse response function, that is, the transfer function:

$$\tilde{K}(x, \omega) = \frac{\hat{R}_\infty}{b(\omega)} e^{-b(\omega)x/\hat{\lambda}} \quad (7)$$

where $\hat{R}_\infty$ is the input resistance (in ohm) of a passive infinite cable, which includes the contribution of the active current to the resting conductance (but does not take into account the dynamics of the active current): $\hat{R}_\infty = \sqrt{R_a / (g_l + \bar{g}_w w_\infty(V_R))} \pi^2 d^3$ with intracellular resistivity R_a (in ohm cm) and cable diameter d (in cm). Note that we defined the transfer function in units of ohm and hence $\tilde{K}(x, \omega)$ is the transfer impedance (or input impedance when $x = 0$).

The response at location x to input current $I(t)$ at the origin can now be obtained by convolving the input with the impulse response function. Since it is not feasible to determine the inverse Fourier transform of $\tilde{K}(x, \omega)$, we make use of the convolution theorem:

$$\begin{aligned} V(x, t) &= K(x, t) * I(t) \\ &= \mathcal{F}^{-1} \left\{ \tilde{K}(x, \omega) \cdot \tilde{I}(\omega) \right\} \end{aligned} \quad (8)$$

where $*$ is the convolution operator and $\mathcal{F}^{-1}\{z\}$ denotes the inverse Fourier transform of z .

Frequency-Dependent Response of Quasi-active Cable

Having obtained the transfer function Eq. 7, we can describe the frequency-dependent input filtering by the quasi-active cable (Fig. 1). The amplitude of the signal at location x resulting from a

sinusoidal input current with frequency ω at the origin is

$$|\tilde{K}(x, \omega)| = \frac{\hat{R}_\infty}{|b(\omega)|} e^{-\operatorname{Re}\{b(\omega)\}x/\hat{\lambda}} \quad (9)$$

where $|z|$ is the modulus and $\operatorname{Re}\{z\}$ is the real part of the complex number z . Thus, a sinusoidal signal decays exponentially along the quasi-active cable with frequency-dependent space constant $\hat{\lambda}/\operatorname{Re}\{b(\omega)\}$ (Fig. 1a). Hence, the steady state voltage attenuation to a step current decays with space constant $\hat{\lambda}/\sqrt{1-\phi}$, which shows that the space constant is decreased by restorative currents and increased by regenerative currents.

The phase shift of the response at location x relative to the phase of the injected current is

$$\arg\{\tilde{K}(x, \omega)\} = \arctan \frac{\operatorname{Im}\{b(\omega)\}}{\operatorname{Re}\{b(\omega)\}} + \operatorname{Im}\{b(\omega)\} \frac{x}{\hat{\lambda}} \quad (10)$$

where $\arg\{z\}$ is the argument and $\operatorname{Im}\{z\}$ is the imaginary part of the complex number z . Thus, the phase shift or delay (in s) of the steady state response to a sinusoidal signal changes linearly along the cable with slope $\operatorname{Im}\{b(\omega)\}/\lambda\omega$ (Fig. 1b).

Advantages and Limitations of Approach

The linear quasi-active approximation naturally does not capture the full dynamics of a cable with nonlinear voltage-dependent membrane conductances. The approximation is mathematically valid for small-amplitude voltage fluctuations around a fixed mean membrane potential; however, in practice those fluctuations can be quite large (10–20 mV), mostly depending on how well the membrane current in question can be approximated by a linear current–voltage relationship over the voltage range of interest. In any case, the quasi-active description of dendritic cables serves as a solid reference to understand how voltage-dependent membrane currents affect input integration in dendrites, and with this method the linear versus nonlinear effects of such currents can be identified. The description reduces the system to the essential parameters and thereby highlights that there are effectively two types of currents: regenerative currents (such as the persistent sodium current) and restorative currents (such as the hyperpolarization-activated inward h-type current; see also Hutcheon and Yarom 2000). Compared to a passive cable, regenerative currents

Quasi-active Approximation of Nonlinear Dendritic Cables, Fig. 1 Frequency-dependent filtering in a quasi-active cable. (a): Frequency-dependent space constant of a cable with an additional current that is regenerative ($\phi = 0.5$), passive ($\phi = 0$), or restorative ($\phi = -2$). The cable has passive space constant $\hat{\lambda} = 500\mu\text{m}$ and membrane time constant $\hat{\tau} = 10\text{ms}$. The active current has activation time constant $\tau_w = 10\text{ms}$. Note that in a cable with a

restorative current, the space constant can have a local maximum at a nonzero frequency. (b): Frequency-dependent delay per space constant of the steady state response to a sinusoidal signal for the same conditions as in a. Note that in a cable with a restorative current, the delay can be zero (i.e., synchronous response of the entire cable) or even negative (i.e., the response at the input site lags behind the neighboring cable)

make the cable electrotonically more compact (less voltage attenuation) and slow down the membrane response, whereas restorative currents increase the electrotonic length of the cable (stronger voltage attenuation) and lead to a faster membrane response (see Koch 1984; Remme and Rinzel 2011). Naturally, the quasi-active approximation can also be applied to cables with multiple voltage-dependent currents and/or currents that have multiple gating variables (see Coombes et al. 2007; Remme and Rinzel 2011). Finally, the approximation also allows one to use other linear methods, for example, the sum-over-trips method, which is used to compute the voltage response of a branched dendritic tree to current input (Coombes et al. 2007).

Definition

Molecular imaging (MI) is a biomedical research discipline enabling the visualization, characterization, and quantification of biological processes taking place at the cellular and subcellular levels within intact living subjects including patients. MI typically includes two- or three-dimensional imaging as well as quantification over time. The MI techniques may include radiotracer imaging/nuclear medicine (such as positron emission tomography (PET) and single-photon emission computed tomography (SPECT), magnetic resonance imaging (MRI), magnetic resonance spectroscopy (MRS), optical imaging, ultrasound, and others.

Radiopharmaceuticals are drug molecules (containing radioactive atoms or radioisotopes) useful for noninvasive imaging studies or radionuclide therapy.

Nuclear medicine (PET and SPECT) uses radiopharmaceuticals as molecular imaging probes that produce signals by means of radioactive decay.

Detailed Description

Elements and Atoms

Everything in this universe is made up of *matter* and *energy*. Matter is anything that has *mass* and occupies space. In contrast, light and heat are forms of energy. All matter in nature is made up of pure substances, known as chemical elements, which are the building blocks of all types of matter. The modern periodic table of elements lists 114 confirmed elements. The first 98 elements exist naturally although some are found only in trace amounts and were initially discovered by synthesis. Of the 98 elements that occur naturally, 84 are primordial. The other 14 elements occur only in decay chains of primordial elements.

From the point of view of chemistry, the smallest unit of an element is the atom of an element representing the chemical identity of that element. The atom consists of a dense central nucleus surrounded by a cloud of negatively charged electrons. The atomic nucleus contains a mix of positively charged protons and electrically neutral neutrons (except in the case of hydrogen-1, which is the only stable nuclide with no neutrons). An atom is classified according to the number of protons and neutrons in its nucleus: the number of protons (*atomic number*, Z) determines the chemical element, while the total number of protons and neutrons (*mass number*, A) determines the isotope (or nuclide) of the element. The electrons of an atom are bound to the nucleus by the electromagnetic force. Likewise, a group of atoms can remain bound to each other by chemical bonds based on the same force, forming a molecule.

Isotopes and Radioisotopes

An isotope and/or nuclide is specified by the name of the particular element (this indicates the Z implicitly). An element may have several isotopes with the same Z , but different A . Most naturally occurring isotopes are stable, while some isotopes undergo spontaneous radioactive decay or transmutation and are therefore described as radioisotopes or radionuclides. Of the known chemical elements, 80 elements have at least one stable nuclide. For example, carbon has two stable isotopes (^{12}C , ^{13}C) and two important radioactive isotopes (^{11}C , ^{14}C). The most important elements and their useful radioisotopes for developing PET and SPECT radiopharmaceuticals are shown in Table 1.

Radioactivity

Radioactive decay, also known as nuclear decay or radioactivity, is the state, property, or process of being radioactive with a spontaneous emission of a stream of particles or electromagnetic rays by unstable atomic nuclei.

Radioactive decay is the process by which a nucleus of an unstable atom loses energy by emitting radiation in order to become a more stable atom.

Types of Radioactive Decay

The stability of an atomic nucleus depends on the neutron/proton (n/p) ratio. There are many different types of radioactive decay depending on whether the nuclide is neutron deficient or neutron rich. The radioactive decay processes, however, falls into two categories: those in which both the parent and the daughter radionuclides have the same mass number (isobaric decay) and those that involve change in mass number (A) of a radionuclide. The five major kinds of radioactive decay are shown in Table 2. Neutron-rich radionuclide generally undergoes β^- decay and increases the atomic number ($Z + 1$). In contrast, the neutron-deficient radionuclide may decay by positron (β^+) emission or by an electron capture (*EC* or *K capture*). In either case, the daughter radionuclide will have one less proton ($Z-1$).

Radiopharmaceuticals in Molecular Imaging, Table 1 Important elements and their useful radioisotopes for PET and SPECT

Element	Atomic number	Stable isotope	Natural abundance (%)	Useful radioisotopes	Decay mode
Carbon	6	^{12}C	98.9	^{11}C	β^+
		^{13}C	1.10		
Nitrogen	7	^{14}N	99.634	^{13}N	β^+
		^{15}N	0.366		
Oxygen	8	^{16}O	99.762	^{15}O	β^+
		^{17}O	0.038		
		^{18}O	0.200		
Fluorine	9	^{19}F	100	^{18}F	β^+
Copper	29	^{63}Cu	69.17	^{62}Cu	β^+
		^{65}Cu	30.83	^{64}Cu	β^+ , β^- , EC
				^{67}Cu	β^- , γ
Gallium	31	^{69}Ga	60.1	^{66}Ga	β^+ , EC, γ
		^{71}Ga	39.9	^{67}Ga	EC, γ
				^{68}Ga	β^+ , EC, γ
				^{72}Ga	β^- , γ
Bromine	35	^{79}Br	50.69	^{75}Br	β^+ , EC
		^{81}Br	40.31	^{77}Br	EC, γ
Rubidium	37	^{85}Rb	72.165	^{82}Rb	β^+
		^{87}Rb	27.845		
Yttrium	39	^{89}Y	100	^{86}Y	β^+ , EC, γ
				^{87}Y	EC, γ
Zirconium	40	^{90}Zr	51.45	^{89}Zr	β^+ , γ
		^{91}Zr	11.22		
		^{92}Zr	17.15		
		^{94}Zr	17.38		
		^{96}Zr	2.80		
Technetium	43	—	—	$^{94\text{m}}\text{Tc}$	β^+
				$^{99\text{m}}\text{Tc}$	IT, γ
Indium	49	^{113}In	4.3	^{111}In	EC, γ
		^{115}In	95.7		
Iodine	53	^{127}I	100	^{123}I	EC, γ
				^{124}I	β^+ , EC, γ
				^{131}I	β^- , γ

Radiopharmaceuticals in Molecular Imaging, Table 2 Types of radioactive decay

Decay mode	Reason for instability of parent nucleus	Transformation	Example	N/P ratio change
Alpha decay	Too large	${}_Z^AX \rightarrow {}_Z - 2^{A-4}Y + {}_2^4\alpha$	${}_{88}^{226}\text{Ra} \rightarrow {}_{88}^{226}\text{Rn} + {}_2^4\alpha$	Increases
Beta decay	Neutron rich	${}_Z^AX \rightarrow {}_{Z+1}^AY + e^-$	${}_6^{14}\text{C} \rightarrow {}_7^{14}\text{N} + e^- + \nu$	Decreases
Positron emission	Neutron deficient	${}_Z^AX \rightarrow {}_{Z-1}^AY + e^+$	${}_6^{11}\text{C} \rightarrow {}_5^{11}\text{B} + e^+ + \nu$	Increases
Electron capture	Neutron deficient	${}_Z^AX + e^- \rightarrow {}_{Z-1}^AY$	${}_{49}^{111}\text{In} + e^- \rightarrow {}_{49}^{111}\text{Cd}$	Increases
Isomeric transition	Excess energy	${}_Z^AX^* \rightarrow {}_Z^AY + \gamma$	${}_{43}^{99\text{m}}\text{Tc}^* \rightarrow {}_{43}^{99}\text{Tc} + \gamma$	No change

Alpha decay is generally seen in high atomic number elements such as ^{238}U and ^{226}Ra . The radionuclide ejects an α particle or a He nucleus (2 protons and 2 neutrons) is converted into a nuclide with a lower atomic number ($Z-2$). Two radionuclides of an element that differ only in the energy content are called *isomers* and the metastable states (half-life $>10^{-12}$ s) are called isomeric states (designated with letter *m* next to A). *Isomeric transition* involves emission of gamma (γ) photons from a radionuclide in metastable state.

Radioactive Decay Equations

Radioactive decay or transformation is a statistical process that obeys the laws of chance. No cause-effect relationship is involved in the decay of any radionuclide, only a certain probability per unit time. The activity (**A**) of a sample of any radionuclide is the rate at which the nuclei of its constituent atoms (**N**) decay. Also the activity (**A**) or the disintegration rate of a radionuclide at any time is proportional to the total number of radioactive atoms present at that time. Mathematically, rate of decay (**A**) is given by

$$A = -\frac{dN}{dt} \propto N \quad (1)$$

$$N = N_0 e^{-\lambda t} \quad (2)$$

$$A = -\frac{dN}{dt} \lambda N \quad (3)$$

$$A_t = A_0 e^{-\lambda t} \quad (4)$$

In the above equations, *N* is the number of radioactive atoms, and λ is the *decay constant* (or proportionality constant) that is defined as the probability of disintegration per unit time. The Eqs. 3 and 4 represent *exponential decay* of any radionuclide and the factor $e^{-\lambda t}$ is known as the *decay factor*, the fraction of original activity A_0 remaining after time *t*.

Units of Activity

The SI unit of radioactivity is named after Becquerel

$$1 \text{ Becquerel} = 1\text{Bq} = 1 \text{ decay/s} \quad (5)$$

The traditional unit of activity is the Curie (Ci), originally defined as the activity of one gram of radium, ^{226}Ra .

Curie is now defined as

$$1 \text{ Curie} = 1 \text{ Ci} = 3.7 \times 10^{10} \text{ dps} \\ = 37 \text{ GBq} \quad (6)$$

$$1 \text{ milliCurie} = 1 \text{ mCi} = 3.7 \times 10^7 \text{ dps} \\ = 37 \text{ MBq} \quad (7)$$

$$1 \text{ milliCurie} = 1 \mu\text{Ci} = 3.7 \times 10^4 \text{ dps} \\ = 37 \text{ MBq} \quad (8)$$

Half-Life and Average Life Time

Every radionuclide has a characteristic half-life ($T_{1/2}$), which is the time required for the activity to decay to 50% of its original value. That is, A_0 is reduced to $A_0/2$ in one half-life, $A_0/2^2$ in 2 half-lives, and $A_0/2^n$ in *n* half-lives. The activity **A** of a radionuclide at any time *t* is given by

$$A_t = \frac{A_0}{2^n} = \frac{A_0}{2^{(t/T_{1/2})}} \quad (9)$$

$$T_{1/2} = \frac{\ln(0.2)}{\lambda} = \frac{0.693}{\lambda} \quad (10)$$

In a given sample of radionuclide, all atoms do not decay with the same half-life; some atoms may have shorter and some atoms may have longer life span than one half-life. The average or mean life (τ) of a radionuclide is therefore defined as the average of all individual life times of that the atoms in a sample of radionuclide experience. The mean life is related to decay constant and half-life:

$$\tau = \frac{1}{\lambda} = \frac{T_{1/2}}{0.693} = 1.44 T_{1/2} \quad (11)$$

Specific Activity (SA)

The SA of a radioactive sample is defined as its activity per unit mass or the ratio of activity (**A**) to the total mass (**m**) of the element present. SA (**A/m**) has units of Ci/g, Ci/mmol, or GBq/mmol, etc. When stable isotopes of an element are present

along with the radioactive isotope, then the stable isotopes are called *carrier*. The radioactivity of the sample is said to be with carrier and the SA of such a radioisotope is low since the total mass of the element includes the mass of radioisotope and also that of carrier. A radioactive sample that does not contain carrier is called *carrier-free*. The highest possible SA of a radionuclide is its carrier-free SA (CFSA). It is also known as the theoretical SA and not necessarily achieved practically by radionuclide production methods. For a number of radioisotopes, the CFSA are shown in the Table 3. CFSA can be calculated since there is a well-defined activity–mass relationship based on the following mathematical relationships:

- Knowing the activity (Ci or GBq, etc.) and λ , the number of atoms (N) in a sample of radioactivity can be determined based on activity law, $A = \lambda N$.
- Based on N, the mass (g or moles) of a radioisotope can be determined since one mole (gram atomic weight) of any element contains 6.022×10^{23} atoms (Avogadro’s number).

Radionuclide Production: Nuclear Reactions

When two nuclei come close together, a *nuclear reaction* can occur that results in *nuclear*

transformation, the conversion of one element to another. In a nuclear reaction, when the atoms of a stable element (target) are bombarded by a subatomic particle (projectile), the nucleus of the stable atom absorbs the subatomic particle. The resultant *compound nucleus* is very unstable and excited. The compound nuclei have life times in the order of 10^{-16} s or so. The compound nucleus may decay in one or more ways, depending on its neutron/proton ratio and excitation energy. It may quickly decompose by emitting some radiation (subatomic particle and/or gamma radiation) to form an unstable product radionuclide. The general equation for a nuclear reaction can be written as follows:

$$T(P,R)Y \tag{12}$$

where *T* represents the target nuclide; *P* is the projectile, the incident, or the bombarding particle; *R* represents the radiation (subatomic particle or γ photons) emitted by the compound nucleus; and finally *Y* represents the product unstable radionuclide. The *P* and *R* in parenthesis, written as (*P, R*), represent the nuclear reaction. A number of reactions such as (*p, n*), (*p, α*), and (*d, α*) are some of the common nuclear reactions used to produce artificial radioisotopes in a cyclotron.

Radiopharmaceuticals in Molecular Imaging, Table 3 Radionuclides for PET and SPECT: half-life and specific activity (SA)^a

Radionuclides for PET			Radionuclides for SPECT		
Nuclide	T _{1/2} (min)	SA (Ci/ μ mol)	Nuclide	T _{1/2} (min)	SA (Ci/ μ mol)

	¹²³ Xe (T _{1/2} = 2.08 h) → ¹²³ I		
¹²⁴ I	¹²⁴ Te(p, n) ¹²⁴ I	73	¹²⁴ I as NaI
	¹²⁴ Te(d, 2n) ¹²⁴ I		

The most widely used particle accelerator is the *medical cyclotron*, which is capable of accelerating protons to low and medium energy levels (10–20 MeV) needed for the production of PET radionuclides (Ruth 2003; Schlyer 2003). Certain cyclotrons also have a deuteron (proton + neutron) beam capability. The commercial cyclotrons with higher-energy proton beams (>30 MeV) are needed to produce proton-rich radionuclides that decay by electron capture. The most important nuclear reactions used in the production of radionuclides are summarized in Table 4.

Radionuclide Generators

When a sample of radioactivity consists of a pair of parent and daughter radionuclides, the daughter is continuously produced by the decay of the parent, and at the same time, the daughter activity is also decaying. The *Bateman equation* (Eq. 13) describes the parent–daughter relationship and provides an estimate of A_d:

$$A_{d(t)} = A_{p(t_0)} \frac{\lambda_d}{\lambda_d - \lambda_p} (e^{-\lambda_p t} - e^{-\lambda_d t}) + A_{d(t_0)} e^{-\lambda_d t} \tag{13}$$

At equilibrium, the parent and daughter activities appear to decay with the same rate, even if the two nuclides have different half-lives. Two

different equilibrium conditions (secular and transient), however, may exist depending on how short lived the daughter radionuclide compared to the parent. If the parent is short lived compared to the parent, then there is no equilibrium at all. If the parent and daughter nuclides are two different elements, they can be separated chemically and the daughter radioactivity can be obtained in high SA. Such a parent–daughter radionuclide pair is ideal to build a generator system to produce daughter radionuclide, when needed (Welch and McCarthy 2000). The *radionuclide generator* is a device to separate the daughter radionuclide from the parent radionuclide. All kinds of physico-chemical separation methods (such as distillation, liquid/liquid extraction) may be used. A chromatographic method based on an inorganic or resin adsorbent material, however, is the most practical method for routine clinical utility. Three important generator systems (Table 5) are available to produce radionuclides of clinical interest.

Radiopharmaceuticals

Radioactivity Versus Chemistry

Radioactivity is a process involving primarily the decay of an unstable nucleus of an element, whereas all the chemical reactions of an element

Radiopharmaceuticals in Molecular Imaging, Table 5 Radionuclide generators

Parent				Daughter			Generator	
Nuclide	T _{1/2}	Decay	NR	Nuclide	T _{1/2}	Decay	Column	Eluent
⁹⁹ Mo	66 h	β [−]	²³⁵ U fission	^{99m} Tc	6 h	IT	Al ₂ O ₃	0.9% saline
⁶⁸ Ge	271 day	EC	⁶⁹ Ga(p, 2n) ⁶⁸ Ge	⁶⁸ Ga	68 min	β ⁺	TiO ₂	1 N HCl
⁶² Zn	9.3 h	EC, β ⁺	⁶³ Cu(p, 2n) ⁶² Zn	⁶² Cu	9.7 min	β ⁺	Dowex	2 N HCl

involve the outermost orbital electrons. Atoms of different isotopes of an element, both stable and radioactive, will have similar chemistry regardless of the radioactive emissions from an unstable nucleus. Similarly, the chemistry of an atom does not affect in any way the radioactive decay characteristics of an atom. The *tracer principle* in nuclear medicine is based on the fact that the chemistry and physiological behavior of radioisotopes of an element are identical to the corresponding naturally occurring stable isotopes of that element.

Radiotracer and Radiopharmaceutical

A radiotracer can be defined as a specific radio-labeled molecule (or probe) that resembles or traces the *in vivo* behavior of a natural molecule and can be used to provide information about a specific biological process. The degree of similarity between radiotracer and the natural substance, however, may vary depending on the particular radiotracer. For example, [¹¹C]glucose and [¹⁴C]glucose are true tracers of glucose since they are chemically identical to natural glucose, while [¹⁸F]fluorodeoxyglucose (FDG), an analog of glucose, also traces glucose, but does not behave identically to glucose since it is chemically different. One of the most important characteristics of a true radiotracer, however, is the ability to study the components of a homeostatic system without disturbing their function. Occasionally, the term *radioligand* is also used in the context of imaging studies. Radioligand can be defined as any radio-labeled molecule that can bind with another molecule or substance (binder) in a predictable way under controlled conditions. For example, [¹¹C]raclopride is a radioligand that binds specifically to dopamine D₂ receptors, while [¹⁸F]FDG is a radiotracer to image glucose metabolism.

All radiolabeled compounds or substances used for the purpose of diagnosis or therapy have been defined as *radioactive drugs* or *radiopharmaceuticals* by the US Food and Drug Administration (FDA). Diagnostic radiopharmaceuticals, however, are administered in trace amounts (<100 μg) and, typically, do not induce any physiological response or pharmacological effect in patients. In addition, FDA adopted the same regulations for radiolabeled compounds (or nuclear medicine imaging probes) as those in existence for traditional drugs (pharmaceuticals). As a result, the term radiopharmaceutical has become the official FDA categorization for all radioindicators and radiotracers used for diagnosis and therapy. Although, the field of nuclear medicine evolved into a more sophisticated molecular imaging technology, the FDA continues to extend the usage of the term radiopharmaceuticals to include the novel radiolabeled molecular imaging probes (RMIPs) also. From a regulatory point of view, however, a radiopharmaceutical must also be sterile, pyrogen-free, safe for human use, and efficacious for a specific indication.

Choice of Radionuclide

A number of radionuclides that emit either a β⁺ or a γ photon are available (Table 6) for radiopharmaceuticals for PET or SPECT. These radionuclides basically belong to four groups of chemical elements: organic elements (C, N, and O), halogens (F, Br, and I), metals (Ga and In), and transition metals (such as Cu, Y, Zr, and Tc). Only certain elements (I, Ga, Cu) have radioisotopes useful to develop radiopharmaceuticals for both PET and SPECT. The organic radionuclides that decay by positron emission are ¹¹C, ¹³N, and ¹⁵O. These three radionuclides are isotopes of

Radiopharmaceuticals in Molecular Imaging, Table 6 Radionuclides useful for developing PET and SPECT radiopharmaceuticals

Elements	For PET				For SPECT		
	Radionuclide	T _{1/2}	Positron (β^+)		Radionuclide	T _{1/2}	γ energy (MeV)
			E (MeV)	Branching

natural elements that are part of the majority of biochemicals and drugs. Among the halogens, fluorine atom is the only one that closely mimics the hydrogen atom in size (Park et al. 2001). The van der Waals' radii of fluorine and hydrogen are very similar, 1.35 and 1.2 Å, respectively. As a result, one can expect that in any given organic molecule, C–F bond closely mimics the biological behavior of C–H bond. In addition, fluorine atom is also the most electronegative of all halogens. As a result, fluorine atom introduces a polarity more akin to a hydroxyl substituent in a molecule. The other halogens are bigger in size and are less electronegative compared to fluorine. As a result, labeling a biochemical with bromine or iodine radioisotopes would alter the biological behavior of the molecule. However, halogen atoms in drug molecules are quite common, and sometimes, the halogen-containing drug molecules may have even greater affinity for a receptor or an enzyme in vivo than the non-halogenated molecules (Park et al. 2001). In the last 2 decades, several

radiotracers were developed based on ¹²³I for SPECT imaging studies of brain. Organic molecules containing aromatic ring can be labeled easily with radioisotopes of iodine. As a result, ¹²³I and ¹²⁴I will play a major role in the development of molecular imaging probes. Among the metals, Ga, In, and Y are trivalent and have similar chemistries. The transition metals such as Cu, Sc, Zr, and Tc have complex coordination chemistries. The radionuclides of all these metals (⁶⁸Ga, ⁶⁴Cu, ⁸⁶Y, ⁸⁹Zr, ¹¹¹In, and ^{99m}Tc) can be used to label small molecules, peptides, and proteins using bifunctional chelating agents.

Radionuclide: Positron (β^+) Versus Gamma (γ) Emission

A positron ejected by a radionuclide travels a very short distance in a tissue, dissipating its kinetic energy in collisions with electrons, and finally combines with an electron to form a positronium, a state which lasts for a very short time (10^{-10} s), and the subsequent positron–electron annihilation

results in the emission of two 511 KeV photons, 180° apart. A PET scanner is designed to detect this pair of annihilation photons almost simultaneously based on a process known as annihilation coincidence detection (ACD). Positron-emitting radionuclides differ in the energy of emitted positrons. For example, the energy of positrons emitted by ^{18}F ($E_{\text{max}} = 0.63$ MeV) is almost 1/7th compared to that of a positron emitted by ^{66}Ga ($E_{\text{max}} = 4.153$ MeV). Positron range is the direct distance traveled by positron from the decaying atom to the exact location of annihilation event. Positron range is a function of the energy of positron (Table 6). The mean positron range may vary from 1 to 4–6 mm depending on the radionuclide. The error due to positron range may be significant, and therefore, positron range limits the ultimate resolution attainable by PET. In addition, the number of positrons emitted (the branching ratio) also changes among different positron emitters (97.86% for ^{18}F compared to 17.5% for ^{64}Cu). It is very important to appreciate that SPECT technique inherently offers no limitation in spatial resolution since γ photons are emitted directly by the nucleus of a SPECT radionuclide ($^{99\text{m}}\text{Tc}$, ^{111}In , ^{123}I). The abundance of γ emission from SPECT radionuclides is more than adequate (>80%). Molecular imaging by PET technique, however, is inherently quantitative, while SPECT offers relatively poor resolution (8–10 mm) and is semiquantitative.

Radiochemistry: Synthesis of Radiopharmaceuticals

Radiolabeling is the chemical reaction during which the radionuclide is incorporated in the desired molecule. The position of a radionuclide in a radiopharmaceutical must be carefully selected so that the presence of radionuclide at that position preserves the overall chemical and pharmacological properties of the parent unlabeled molecule. In addition the position of radiolabel must also preserve the metabolic stability of the radiotracer during the time course of an imaging study. In addition, specific activity, stereospecificity, lipophilicity, and plasma protein binding are all important in the overall design of any radiopharmaceutical. Depending on the type

of radioisotope chosen and the method used to radiolabel a specific molecular imaging probe, three different methods may be utilized in the synthesis of radiopharmaceuticals:

1. *Isotope exchange*: A radiopharmaceutical may be prepared by direct exchange (isotopic substitution) of one or more stable atoms of an element in a molecule with one or more radioisotopes of the same element. The radiolabeled molecule and the unlabeled molecule are chemically identical and behave in vivo in a similar manner. In the preparation of ^{11}C -labeled radiotracers, the Stable ^{12}C atom is replaced by ^{11}C radionuclide. The preparation of ^{11}C compounds, however, may involve multistep alkylation reactions. The method of isotope exchange radiolabeling is generally used to prepare radioiodinated radiopharmaceuticals in which the Stable ^{127}I atom is replaced by ^{123}I or ^{124}I tom.
2. *Introduction of a foreign element*: A radiopharmaceutical may be prepared by the introduction of a foreign element or radionuclide in a parent molecular imaging probe. Most of the radiopharmaceuticals are prepared based on this method. The radiotracer may not be chemically identical to unlabeled molecule and may have different in vivo behavior. For example, preparation of [^{18}F]FDG involves the introduction of ^{18}F atom in deoxyglucose molecule. Also in the preparation of radioiodinated peptides and hormones, ^{123}I or ^{124}I is added to the parent molecules that do not contain natural stable iodine atom.
3. *Metal chelation*: This method also introduces a foreign element (radiometal such as $^{99\text{m}}\text{Tc}$, ^{64}Cu , ^{68}Ga , and ^{111}In) into an organic molecule known as chelating agent. One or more atoms (such as O, N, and S) in the chelating agent donate a pair of electrons to the foreign metal atom to form coordinate covalent bonds. As a result, the chemical and biological properties of the radiometal-chelate complex are different compared to the chelating agent. Certain peptides and proteins such as monoclonal antibodies can be labeled with radiometals based on the metal chelation method described

above. This technique, however, requires conjugation of a bifunctional chelate (BFC) to the peptide or protein first and then subsequent chelation of the radiometal by the BFC molecule. In general, radiometals are not directly incorporated into the peptide or protein molecule. However, proteins like transferring may have specific binding sites to metals like iron and gallium.

In this chapter on radiopharmaceuticals for neuroimaging studies, an overview of the most common chemical approaches for the synthesis of PET and SPECT radiotracers are discussed with special emphasis on the most recent developments and trends. The major emphasis, however, is on PET radionuclides, especially ^{11}C and ^{18}F .

^{11}C -Labeled Radiopharmaceuticals

Carbon is one of the main constituents in most molecules of biological importance. Hence, labeling with ^{11}C will result in radiotracers indistinguishable from their non-labeled counterparts. There are several disadvantages of using ^{11}C radionuclide. Because of its short half-life (20 min), the synthesis of ^{11}C -labeled radiotracer, purification, and quality control testing has to be performed very rapidly (in <1 h) in order to have optimal specific activity for receptor imaging studies. Also because of short half-life, commercial distribution of ^{11}C radiotracers by commercial radiopharmacies is not very difficult and can only be done at academic research facilities. $[^{11}\text{C}]\text{CO}$ was the first radiotracer used in human subjects to investigate the fixation of CO by red blood cells. Several reviews discussed extensively the

chemistry and potential application of ^{11}C -labeled radiotracers (Antoni and Långström 2005; Dollé 2013; Långström et al. 2013).

The most commonly used method of ^{11}C production is based on the nuclear reaction, $^{14}\text{N}(\text{p},\alpha)^{11}\text{C}$, in which the natural nitrogen gas is used as the target. With trace amounts of oxygen in the target (<1%), the $[^{11}\text{C}]\text{CO}_2$ and $[^{11}\text{C}]\text{CO}$ are formed. With relatively higher proton energies (>13 MeV), longer irradiation times (>30 min), and higher beam currents (>30 μA), the most predominant ^{11}C precursor generated is $[^{11}\text{C}]\text{CO}_2$ gas. In the presence of hydrogen (5%) in the target, $[^{11}\text{C}]\text{methane}$ (CH_4) and $[^{11}\text{C}]\text{hydrogen cyanide}$ (HCN) can be produced in the target by a recoil synthesis, but due to radiolysis, $[^{11}\text{C}]\text{CH}_4$ is the main precursor available for processing. The theoretical SA of ^{11}C is 9.22 Ci/nmol. The contamination of the target and the gas lines with Stable ^{12}C is unavoidable. As a consequence, the practical SA of ^{11}C precursors achieved from typical production in a cyclotron target varies from 0.01 to 0.1 Ci/nmol depending on a number of factors.

$[^{11}\text{C}]\text{Methyl iodide}$ (CH_3I) is the precursor of choice for introducing ^{11}C into organic molecules. Two methods are used for the synthesis of $[^{11}\text{C}]\text{CH}_3\text{I}$ (Fig. 1). In a “liquid-phase” synthesis, $[^{11}\text{C}]\text{CO}_2$ is first reduced using lithium aluminum hydride (LiAlH_4) to methanol $[^{11}\text{C}]\text{CH}_3\text{OH}$, which then reacts with hydroiodic acid (HI) to generate methyl iodide. In a “gas-phase” synthesis, $[^{11}\text{C}]\text{CH}_4$ gas (either from the target directly or produced from $[^{11}\text{C}]\text{CO}_2$) reacts with iodine vapors generating methyl iodide. Commercial automated synthesis modules are available to synthesize $[^{11}\text{C}]\text{CH}_3\text{I}$. *GE MicroLab* and *GE TracerLab FXc Pro* modules were designed to generate methyl iodide based on the gas-phase method

Radiopharmaceuticals in Molecular Imaging,
Fig. 1 Synthesis of $[^{11}\text{C}]$
methyl iodide

A. Liquid Phase

B. Gas Phase

while *Bioscan MeI-Plus* was designed based on the liquid-phase method. [^{11}C]CH $_3$ I can also be used to prepare a number of secondary ^{11}C precursors (Fig. 2) such as methyl triflate, ($\text{CH}_3\text{OSO}_2\text{CF}_3$) methyl lithium, nitromethane, and methyl magnesium iodide or bromide. Starting with [^{11}C]methane, precursors such as hydrogen cyanide, cupric cyanide, carbon tetrachloride, and phosgene can be prepared (Antoni and Långström 2005; Li and Conti 2010). Synthesis of several ^{11}C precursors is shown in Figs. 2 and 3.

In the last three decades, a number of ^{11}C -labeled molecular imaging probes of significant clinical interest have been developed. Historically several different approaches have been developed for the production of ^{11}C -labeled radiotracers, but the most practical approaches have been based on either (a) organic synthetic methods or (b) enzyme catalysis (Antoni and Långström 2005). The methods based on organic synthesis typically involve alkylations of C, N, O, and S nucleophiles with [^{11}C]methyl iodide or methyl triflate. The alkylation

Radiopharmaceuticals in Molecular Imaging,

Fig. 2 ^{11}C precursors

Radiopharmaceuticals in Molecular Imaging, Fig. 3 Synthesis of ^{11}C precursors

reactions require an organic precursor, also known as *nor* compound (a molecule of interest without a methyl group on a specific C, N, O, or S atom). If a molecule of interest has several reactive groups, the organic precursors must have protective groups that can be easily de-protected by hydrolysis following methylation to generate the final drug product. This is the most common synthetic approach used in the routine production of ^{11}C -labeled radiopharmaceuticals.

Several methods for carrying out ^{11}C methylations either in solution or on solid support have been reported in the literature. When methylations are carried out in solution, solvents like DMSO, DMF, acetone, and acetonitrile are generally used. In many cases, a base is needed for deprotonation. Commonly used bases are K_2CO_3 , TBOH, NaOH, and NaH. In general, the precursor is dissolved in the appropriate solvent in the presence of a base. The ^{11}C -methylating agent (methyl

iodide or methyl triflate) is bubbled through the solution and incubated at 70–120 °C. Following HPLC purification the ^{11}C -labeled radiotracer is dissolved in an appropriate isotonic buffer and sterilized by membrane filtration. Representative PET tracers made from this category of reactions are listed in Fig. 4. Methylations on a solid support are very convenient for automation purposes. The precursor is coated on a solid support, such as an HPLC loop or a solid-phase extraction cartridge. The ^{11}C -methylating agent is passed through the solid support. The product is eluted from the support by a solvent or HPLC mobile phase.

$^{11}\text{CO}_2$ has been converted to organometallic Grignard reagents to form $[^{11}\text{C}]$ carboxymagnesium halides and then transformed into $[^{11}\text{C}]$ carboxylic acids. Moreover, enzyme-catalyzed chemical transformations have been employed for the introduction of ^{11}C in amino acids.

Radiopharmaceuticals in Molecular Imaging, Fig. 4 Synthesis of ^{11}C -labeled radiopharmaceuticals

¹⁸F-Labeled Radiopharmaceuticals

¹⁸F is the most often used radionuclide for diagnostic PET imaging since the decay properties of ¹⁸F provide significant advantages. As discussed earlier, labeling a molecule with ¹⁸F in place of a hydrogen atom often does not change its size or shape, and generally metabolically stable compounds are obtained. ¹⁸F appears to be an ideal radionuclide for developing PET radiopharmaceutical in the following reasons:

- Low β^+ energy (0.64 MeV) with a short range in tissue (~2.0 mm) and provides high-resolution images.
- Can be produced in high SA (20–50 Ci/ μ mole).
- Can be produced in large amounts (>10 Ci) in a cyclotron.
- Fluorine is the most electronegative and can react with many organic and inorganic chemicals.
- It can react as an electrophile or a nucleophile chemical species.
- Relatively high labeling yields (20–70%) in the synthesis of ¹⁸F-PET tracers.
- Acceptable radiation dosimetry for multiple studies in a patient.
- The physical $T_{1/2}$ (110 min) allows for transport from the production site to the PET centers.

The design and synthesis of ¹⁸F-labeled radiopharmaceuticals of clinical interest has been extensively reviewed previously in several publications (Vallabhajosula 2009; Li and Conti 2010). Some of the basic principles of ¹⁸F chemistry are briefly described below.

Radiofluorination

In addition to the two primary ¹⁸F precursors (fluoride and fluorine gas), several secondary precursors have been developed to radiolabel a number of organic molecules (Fig. 5). Fluoride ion needs to be activated (discussed below) prior to fluorination reactions. Metal fluorides (such as K¹⁸F, Cs¹⁸F) and tetra-n-butyl ammonium fluoride (nBu₄N¹⁸F) are the most widely used ¹⁸F precursors in nucleophilic fluorination reactions, while [¹⁸F]CH₃COOF (acetyl hypofluorite) is the most common precursor in the electrophilic reactions. The main synthetic strategies could be divided into two categories: (1) direct fluorination (the ¹⁸F isotope is introduced “directly” into the target molecule of interest) and (2) indirect fluorination (the ¹⁸F isotope is introduced through ¹⁸F prosthetic groups, which usually requires a multi-step synthetic approach).

Nucleophilic Fluorination Reactions

The most successful approach for preparing high SA ¹⁸F radiotracers is based on nucleophilic fluorination reactions. Synthesis of ¹⁸F radiotracers using fluoride ion utilize 2 general types of chemical reactions: (a) aliphatic nucleophilic substitution or substitution nucleophilic bimolecular (S_N2) and (b) aromatic nucleophilic substitution (S_NAr). In aliphatic S_N2 reactions, the fluoride ion attacks and binds to the carbon atom of the substrate at 180° opposite to a leaving group (Fig. 6) that is a weak base (such as iodide, bromide, triflate, tosylate, nosylate, mesylate, etc.). S_NAr nucleophilic reactions were designed to

R

3. Electrophilic fluorination

Radiopharmaceuticals in Molecular Imaging, Fig. 6 Fluorination reactions

incorporate ^{18}F atom directly into the aromatic ring as well as into prosthetic groups containing aromatic ring of a molecule. In these reactions, the leaving group is activated by the electron-withdrawing groups *ortho* and/or *para* to the leaving group, such as halide, NO_2 , and R_3N^+ . The fluoride ion in aqueous solution is very unreactive and has to be activated to increase its solubility and lipophilicity. ^{18}F fluoride ion is generally activated by complexing with a metal or positively charged ion. When alkali metal halides (K^{18}F , Cs^{18}F , Rb^{18}F) are used, it is essential to have the metal to be coordinated by cryptands and polyaminoethers (such as Kryptofix 2.2.2) so that the free fluoride can show very good reactivity. Instead of alkali metal halides, a variety of tetraalkylammonium ^{18}F fluorides have also been used but show low stability at higher temperature. These reactions generally take place in basic or neutral conditions in the presence of an appropriate dipolar

aprotic solvent (such as acetonitrile, dimethyl sulfoxide (DMSO), and dimethylformamide (DMF)) in which the reactants show good solubility. Sometimes, ^{18}F fluoride ion is first converted to another reactive species such as alkyl halides (such as ^{18}F fluorobromoethane, ^{18}F fluorobromopropane) and benzylic halides. A number of ^{18}F radiopharmaceuticals such as ^{18}F FDG and ^{18}F fallypride can all be prepared using commercially available precursors.

Electrophilic Fluorination Reactions

The reaction of ^{18}F F_2 with precursors is accomplished by addition to double bonds or to aromatic rings. The ^{18}F F_2 precursor has only one of the atoms as ^{18}F while the other is Stable ^{19}F atom. Therefore, the labeling yield are always $<50\%$. Since fluorine is a nonselective electrophile, and acts as an oxidizing agent, it is frequently

converted into [^{18}F]acetyl hypofluorite, a milder and much less reactive agent with greater solubility than elemental fluorine. With these precursors, direct electrophilic fluorinations are not necessarily regioselective and the ^{18}F atom can attack any of the C–C double bond in the molecule. Therefore, these precursors are used only in rare situations where nucleophilic reactions are not appropriate. However, regioselective electrophilic fluorodemetalation reactions were developed to take advantage of reactive electrophiles in the preparation of ^{18}F -PET tracers. Electrophilic fluorination reactions (Fig. 6) are facilitated by the presence of electron-donating groups (such as OH, OCH_3 , NH_2 , etc.) and appropriate leaving groups (such as H, SnR_3 , SiR_3 , and HgR) in the precursor molecule. Selectivity can further be increased by using the fluorodemetalation reaction, in which preferentially a trialkyltin group is substituted by electrophilic ^{18}F .

Organic Precursors for ^{18}F Labeling

The synthesis of ^{18}F -labeled PET tracer is a multi-step process and it is ideal to introduce ^{18}F in the last step to reduce synthesis time. In the design of a PET tracer, the most important step is the synthesis of an appropriate precursor of the desired radiotracer, which will facilitate ^{18}F labeling. As discussed above, the ^{18}F reactions require an appropriate leaving group, in the precursor molecule. In addition, the molecules to be labeled may have a number of functional groups (such as OH, COOH , NH_2), which may react and interfere with the labeling of radioisotope in a specific position in a molecule. Therefore, in order to facilitate regioselective labeling of substrates, organic precursors have to be synthesized first with protective groups attached to functional groups. It is very important that the protective groups are very stable during labeling procedure and can be removed rapidly and easily under conditions favorable to maintain the stability of the radiolabeled molecule. A number of precursors for ^{18}F labeling have been developed over the years and are now commercially available. Several examples of precursors with appropriate leaving groups and

protective groups developed for the synthesis of ^{18}F -labeled radiotracers such as [^{18}F]FDG, [^{18}F]fallypride, and [^{18}F]flumazenil are shown in Fig. 7. In case of [^{18}F]FDG, the precursor is mannose triflate, in which the 4 hydroxyl groups of deoxyglucose are protected by adding acetate (Ac) groups. Also, in order to facilitate ^{18}F labeling, a leaving group, trifluoromethane sulfonate (TFMS), is added to the carbon in the second position. In case of [^{18}F]fallypride, the precursor is tosyl fallypride, in which the leaving tosyl group is added to the alkyl side chain. The precursor for the synthesis of [^{18}F]flumazenil is nitromezanil in which the nitro group (NO_2) in the aromatic ring is substituted by the reactive [^{18}F]fluoride ion.

Radioiodination

Unlike fluorine, iodine can exist in several oxidation states. The free molecular iodine (I_2) has the structure of I^+-I^- in aqueous solution. But the electrophilic species (I^+) does not exist as a free species, but forms complexes with nucleophilic entities such as water or pyridine. The reactions with water can be written as follows:

The hydrated iodonium ion, H_2OI^+ , and the hypoiodous acid, HOI, are believed to be the highly reactive electrophilic species. In an iodination reaction, iodination occurs by (a) electrophilic substitution of a hydrogen ion by an iodonium ion in a molecule of interest or (b) nucleophilic substitution (isotope exchange) where a radioactive iodine atom exchanges with a stable iodine atom that is already present in the molecule. In the preparation of radioiodinated compounds, the radioiodine is preferentially attached to a carbon atom, in a vinylic or aromatic moiety, in which the carbon–iodine bond strength

Radiopharmaceuticals in Molecular Imaging, Fig. 7 Precursors for ^{18}F -labeled radiopharmaceuticals

is higher. Therefore, the radioiodination is often implemented by electrophilic or nucleophilic aromatic substitution. Electrophilic labeling reactions can often be performed fast and under mild reaction conditions. The electrophilic species (HO^*I , $\text{H}_2\text{O}^*\text{I}$) generated from radioiodide and the oxidant react directly with the aromatic moiety of the compound to be labeled. Most frequently used oxidizing agents are peracetic acid and the N-chloro compounds, such as chloramine-T, iodogen, and succinimides. The labeling of small organic molecules, peracetic acid, is often preferred due to its mild oxidizing properties. Electrophilic substitutions can often be carried out on a non-derivatized substrate. However, in case of low reactivity or lack of regioselectivity, radioiodo destannylation has become more and more the method of choice. The method of choice in nucleophilic radioiodination is the well-established Cu(I)-catalyzed halogen-halogen exchange reaction in an acidic, aqueous medium. The exchange reactions can be either isotopic exchange ($^*\text{I}/\text{I}$) or non-isotopic exchange

($^*\text{I}/\text{Br}$), which specifically enables the synthesis of a high SA radiopharmaceuticals. A nucleophilic exchange can be successfully applied on activated (presence of electron-deficient substituents, e.g., carbonyl group) or non-activated (e.g., alkyl group) aromatic compounds. However, in organic media, electron-donating substituents are also well tolerated. The advantages and disadvantages of different radioiodination techniques were recently reviewed (Kabalka and Mereddy 2004; Eersels et al. 2005).

Labeling of Biomolecules with Radiometals

The majority of diagnostic SPECT radiopharmaceuticals currently available in nuclear medicine are either radiometal complexes or target-specific biomolecules labeled with metallic radionuclides, such as $^{99\text{m}}\text{Tc}$, ^{67}Ga , and ^{111}In . Metallic radionuclides, such as ^{68}Ga , ^{64}Cu , and ^{89}Zr , are potentially useful to radiolabel biomolecules for PET.

Different radiometals have significant difference in their coordination chemistry. Since the radio-metal chelate can have a significant impact on biological properties, the biodistribution of a target-specific metallic radiopharmaceutical can be systematically changed either by modifying the coordination environment around the radio-metal with a variety of chelators or by the use of various coligands if the radiometal chelate contains two or more ligands.

Both gallium and indium are group IIIB metals and the most prevalent oxidation state in aqueous solution is +3. Due to their high charge density, these two metals prefer hard donors, such as amine-N and carboxylate-O atoms. However, hydrolysis of Ga(III) around physiological pH range remains a significant challenge during radiolabeling (Wadas et al. 2010). The bifunctional chelates (BFC) to develop target-specific radiotracers are polydentate acyclic and macrocyclic chelators such as DTPA, DOTA, and NOTA (1,4,7-triazacyclononane-1,4,7-triacetic acid). To develop ^{68}Ga -labeled radiopharmaceuticals, NOTA is ideal since the thermodynamic stability constant of Ga-NOTA ($\log K = 30.98$) is much higher than that of Ga-DOTA ($\log K = 21.33$).

Copper is a first-row transition metal and its chemistry in aqueous solution is restricted to two oxidation states: Cu(I) and Cu(II). Cu complexes remain stable in aqueous solution only when chelators contain soft donors, such as phosphine-P and thioether-S. The coordination geometry for Cu(I) complexes is almost always tetrahedron and the coordination number is 4, 5, or 6 depending on denticity of the chelator. The design of BFCs for copper radionuclides has been focused on macrocyclic chelators that are able to form Cu(II) complexes with both high thermodynamic stability and kinetic inertness.

Molecular Imaging

Molecular imaging is generally defined as the ability to visualize and quantitatively measure the function of biological and cellular processes in vivo. In addition, molecular imaging aims to integrate patient-specific and disease-specific

molecular information derived from diagnostic imaging studies. The members of the Molecular Imaging Center of Excellence (MICoE) Standard Definitions Task Force recently developed the following standard definitions and terms (Mankoff 2007):

- Molecular imaging is the visualization, characterization, and measurement of biological processes at the molecular and cellular levels in humans and other living systems.
- Molecular imaging agents as “probes used to visualize, characterize, and measure biological processes in living systems. Both endogenous molecules and exogenous probes can be molecular imaging agents.”

The main advantage of in vivo molecular imaging is its ability to characterize diseased tissues without invasive biopsies or surgical procedures. The goal of molecular neuroimaging is the noninvasive visualization and quantification of molecular entities in brain and its correlation to pathophysiological events. Nuclear medicine (PET and SPECT), with the radiolabeled target specific molecular imaging probes (radiopharmaceuticals), can be considered presently as the most sensitive technique for in vivo imaging of the ligand–receptor interactions with picomolar to femtomolar sensitivity. The ultimate goal of brain PET radiotracers is the noninvasive localization and quantification of neuronal metabolism, protein function, neurotransmitter–neuroreceptor interaction, and abnormal protein accumulation in order to get further insight into the mechanisms of molecular pathophysiology associated with various neuropsychiatric diseases and to facilitate the design of diagnostic biomarkers and to speed up the development of new therapeutics. Several hundred radiotracers are listed at the “Molecular Imaging and Contrast Agent Database” (MICAD). A number of radiopharmaceuticals useful for PET and SPECT imaging studies of brain are summarized in Tables 7, 8, and 9.

The brain function is directly related to neural signaling and transmission of electrical activity via chemical and electrical synapses. Neurotransmitters are endogenous chemicals (amino acids,

amines, peptides) that transmit signals from a neuron to a target cell (or another neuron) across a synapse. A neuroreceptor is a membrane receptor protein that is activated by a neurotransmitter. Glutamate is excitatory while GABA is inhibitory at the receptor site. Major neurotransmitter–receptor systems are summarized in Table 10. Neurotransmitters are at the foundation of many psychiatric and neurological disorders, and imbalances in neurotransmission are associated with movement disorders, depression, insomnia, anxiety, behavioral disorders, memory disorders, and many other neurological functions. Because neurotransmitters play an integral role in these disease states, they are prime targets for treating disorders of the nervous system and mental health concerns. In order to optimize the individualized patient treatment based on targeted molecular therapies, selection of appropriate patients for specific drugs needs noninvasive molecular imaging techniques that can quantitatively assess the functional status and the underlying neurotransmitter and/or neuroreceptor abnormalities associated with a specific neuropsychiatric disease or disorders. The major contributions of molecular neuroimaging studies are summarized below:

Neuronal Metabolism

The changes in electrical activity of neurons (excitation or inhibition) have been indirectly attributed to the alterations in the regional cerebral blood flow (rCBF) or local cerebral metabolic rate for glucose (LCMRglc). The functional coupling of rCBF and LCMRglc has been well established in normal human brain and certain neurological diseases. [¹⁵O]water-PET has been the gold standard to assess regional cerebral blood flow (rCBF). The deoxyglucose technique, by employing autoradiography using radiolabeled deoxyglucose ([¹⁴C]DG), opened the way to measure regional cerebral glucose metabolism. The development of [¹⁸F]FDG-PET added a major dimension to the investigation of brain function. FDG is transported into the cell, phosphorylated and, unlike glucose, cannot be metabolized further, and remains trapped within the cytoplasm. Therefore, PET provides insight into energy metabolism in vivo by quantifying glucose consumption, cerebral perfusion, and oxygen consumption. In neuroscience research, this allows the study of neural activity, as well as disease processes, based on the brain's metabolism and

Radiopharmaceuticals in Molecular Imaging, Table 9 Radiopharmaceuticals for molecular imaging studies of brain

Brain Receptors and Transporters

The design, synthesis, and development of molecular neuroimaging radiopharmaceuticals in the assessment of neurotransmission are some of the most active areas of molecular imaging research. Several review articles have discussed the development of receptor binding radiopharmaceuticals and their potential clinical applications (Fowler et al. 2003; Heiss and Herholz 2006; Zimmer and Luxen 2012). The estimation of neuroreceptor occupancy is one of the most

powerful examples of the utility of molecular imaging in CNS drug development and for personalized patient therapy. The potential value of neuroreceptor imaging based on PET was first demonstrated in 1983 using dopamine D_2 receptor ligand $^{[11]\text{C}}\text{N-methylspiperone}$ (Wagner et al. 1983). A primary goal of brain neuroreceptor imaging is to visualize the receptors and involved in neurophysiological and pathological processes. The outcome measures are the density of receptors and the binding affinity of the radioligand binding to the receptor. For PET ligands with high specific radioactivity, the maximum bound/free (B/F) ratio will be equivalent to the receptor concentration/ligand affinity (Bmax/Kd). Brain imaging typically identifies neurotransmitters at three locations in the neurotransmitter pathway:

Radiopharmaceuticals in Molecular Imaging, Table 10 Important neurotransmitters and receptors in brain

Neurotransmitter	Function	Neuroreceptors	Potential role in disease
Dopamine (DA)	Mediation of movement, cognition, and emotion	DA D ₁ to D ₅ receptors	PD, AD, schizophrenia, Huntington's disease
5-Hydroxytryptamine (5-HT or serotonin)	Regulation and modulation of sleep, affective and personality behaviors, and pain	5-HT ₁ to 5-HT ₇ receptors	Depression, anxiety, schizophrenia, obsessive-compulsive disorder, eating disorders
Acetyl choline (ACh)	Mediates complex functions, such as attention, memory, cognition, and consciousness	ACh nicotinic and muscarinic receptors	AD, PD, schizophrenia, Huntington's disease
Norepinephrine (noradrenaline)	Stimulates sympathetic nervous system responsible for fight-or-flight response	Adrenergic (α_2) receptors	AD, movement disorders, and depression. Age-related changes in arousal, mood, and memory
Endorphins	Play an important role in the regulation of analgesia, shock, appetite, thermoregulation, and cardiovascular, mental, and endocrine function	Opiate delta (δ), mu (μ), and kappa (κ) receptors	PD, epilepsy, depression, drug abuse, epilepsy, Tourette's syndrome
Glutamate	Responsible for postsynaptic excitation and are important for neural communication, memory formation, learning, and regulation	Ionotropic and metabotropic glutamate receptors (iGluRs and mGluRs)	Several neurodegenerative diseases. Anxiety, depression, schizophrenia, and drug addiction or withdrawal
N-methyl-d-aspartate (NMDA)	A selective agonist of NMDA critical in synaptic plasticity, a cellular mechanism for learning and memory	The NMDAR is a specific type of iGluR	
γ -Amino butyric acid (GABA)	The chief inhibitory neurotransmitter	GABA _A is the target for benzodiazepines and is known as central benzodiazepine receptor (CBR)	Alzheimer's disease, epilepsy, or cerebral ischemia
Glycine	Modulates the neuroexcitatory activity of the NMDA receptor	Glycine binding site on NMDA receptor	Neuropsychiatric ailments, such as schizophrenia and related disorders
Histamine	Regulates the synthesis and release of histamine itself and other neurotransmitters such as noradrenalin, dopamine, and acetylcholine	Histamine H ₃ receptor	Involved in the development of schizophrenia, epilepsy, ADHD, and AD
Adenosine	In the brain, regulate the release of dopamine and glutamate. Also has a sedative effect	Adenosine (A ₁ , A _{2A}) receptors	Epilepsy, ischemic cerebral stroke, movement disorders, sleep disorders, and psychiatric disorders
Cannabinoid receptors	Endocannabinoids and hallucinogens (such as marijuana) can mimic or block actions of neurotransmitters and interfere with normal functions	CB1 receptors expressed on presynaptic terminals	Range of neuropsychiatric and neurodegenerative disorders

(continued)

Radiopharmaceuticals in Molecular Imaging, Table 10 (continued)

Neurotransmitter	Function	Neuroreceptors	Potential role in disease
Substance P	Modulatory roles in mood, anxiety/stress responses, reward, nociception, emetogenesis, motor control, and neurogenesis	Neurokinin (NK ₁) receptor	Depression. Treatment of emesis, associated with cancer chemotherapy
Nociceptin/orphanin FQ peptide	Regulation of pain, anxiety and depression, drug abuse, feeding, learning/memory, and motor activity	NOP receptor (an opioid receptor)	Treatment of chronic pain

the presynaptic neuron, the postsynaptic neuron, and the intraneuronal metabolism. For example, [¹¹C]PE2i-PET or DaTscan-SPECT provides a measure of dopamine transporter (DAT) density on presynaptic neuron membranes, [¹¹C]raclopride-PET or ¹²³I-IBZM-SPECT measures D2 receptor density on the postsynaptic dopaminergic neuron, and [¹⁸F]FDOPA, the radiolabeled precursor of dopamine, allows imaging of the dopamine metabolic pathway, at a presynaptic intraneuronal level (Brooks 2010).

Enzymes in the Brain

Biologically important processes in normal brain function and brain disease involve the action of enzymes. High-affinity radiolabeled enzyme inhibitors are now serving as tracers for enzymes, particularly for measuring the abundance of enzymes mediating intracellular signal transduction in the brain, and may offer a rich diversity of potential targets for drug discovery. Several radiotracers under clinical evaluation for some of the important enzymes are summarized in Table 7.

Neurodegenerative Diseases (NDDs) and Aggregated Proteins

One of the most active domains in brain PET imaging is currently the field of neurodegenerative disorders, such as Alzheimer’s disease (AD) and Parkinson’s disease (PD) (Någren et al. 2010; Vallabhajosula 2011). Because β-amyloid (Aβ) plaques are the hallmark of Alzheimer’s disease

pathology, a number of radiotracers were developed to measure the brain regional distribution and density of Aβ. [¹¹C]PiB is a sensitive and specific marker for Aβ. Since the short physical half-life of ¹¹C requires that a cyclotron be available on-site, three different ¹⁸F analogs were also developed. Two agents, florbetapir and flutemetamol, were approved by FDA for commercial distribution. NDDs are also characterized by pathological tau (τ) accumulation and are termed “tauopathies,” involving intracellular accumulation of τ protein leading to the so-called neurofibrillary tangles (NFTs) (Goedert et al. 2006). Several new radiotracers such as ¹⁸F-THK5117 and ¹⁸F-T807, specific for PHF-tau, are under clinical investigation.

Neurooncology

Unlike CT and MRI, PET imaging studies in patients with brain tumors give information on the metabolic state and molecular events within the tumor. [¹⁸F]FDG has been the tracer of choice for oncologic PET imaging, based on the increased glucose metabolism of most tumors. However, it has significant limitations for brain tumor imaging due to the normal gray matter uptake of FDG. Neurooncology is a discipline that integrates cancer science and neuroscience. A number of targeted radiopharmaceuticals were developed. Radiotracers such as [¹¹C]choline, [¹¹C]methionine, [¹⁸F]fluoromethyl (or ethyl) tyrosine, and [¹⁸F]fluorothymidine provide significant advantages compared to FDG, for initial diagnosis, tumor grading, and assessment of treatment response (Vallabhajosula 2011).

Neuroinflammation

Classical inflammation response is more and more closely associated with many neurological disorders (e.g., stroke or trauma) when in acute and NDDs when chronic (Cagnin et al. 2007; Glass et al. 2010; Hirsch et al. 2012). A dominant response to all types of CNS injuries is the activation of microglia and astroglia, often referred to as gliosis, at the sites of damage. The inflammatory response in the brain is a double-edged sword. It is a self-defense reaction aimed at eliminating injurious stimuli and restoring tissue integrity. However, inflammation may become a harmful process when it becomes chronic. A major hallmark of microglial activation is the expression of the peripheral benzodiazepine receptor (PBR), also known as the translocator protein. The TSPO expression is nearly absent in resting microglia but rapidly increases during inflammation. This increase in TSPO expression is correlated to the extent of microglial activation. This makes PBR/TSPO a biomarker and an attractive target for the imaging of cerebral inflammation (Ching et al. 2012). (*R*)-[^{11}C]PK11195 is the first nonbenzodiazepine and selective TSPO ligand with nanomolar affinity, and it is the prototypical reference for PBR/TSPO binding. It has been investigated extensively in humans; however, it has low sensitivity and a limited capacity to quantify subtle TSPO expression *in vivo*. Several new TSPO radiotracers with higher affinity, low nonspecific binding, and improved capacities to image and quantify TSPO expression are being evaluated in preclinical models and pilot human studies. Among these new radiotracers, [^{11}C]DPA713, [^{18}F]DPA714, [^{11}C]DAA1106, [^{18}F]FEDAA1106, and [^{11}C]SSR180575 have shown significantly increased binding in the living brain.

Summary

Molecular imaging (MI) is a new biomedical research discipline enabling the visualization, characterization, and quantification of biological processes taking place at the cellular and subcellular levels within intact living subjects including patients. Nuclear medicine (PET and SPECT)

uses radiopharmaceuticals as molecular imaging probes that produce signals by means of radioactive decay. The goal of molecular imaging studies of brain based on PET and SPECT is the noninvasive localization and quantification of neuronal metabolism, protein function, neurotransmitter–neuroreceptor interaction, and abnormal protein accumulation in order to get further insight into the mechanisms of molecular pathophysiology associated with various neuropsychiatric diseases and to facilitate the design of diagnostic biomarkers and to speed up the development of new therapeutics. [^{15}O]Water-PET has been the gold standard to assess the rCBF and [^{18}F]FDG is the most important radiotracer designed to study glucose metabolism. While hundreds of radiotracers were developed for neuroreceptor imaging, ^{123}I -labeled FP-CIT (DaTscan) is the only tracer approved to image presynaptic dopamine receptors in PD. Deposition of protein aggregates (A β and τ protein) with ^{18}F -labeled tracers (florbetapir and flutemetamol) and study of the role of neuroinflammation in NDDs are two major areas of active clinical investigation. The use of imaging biomarkers for the development of drug therapies, a field termed “pharmaco-imaging,” has become more common in recent years. This is particularly advantageous since one can explore brain neurochemistry *in vivo*. There is increasing evidence that PET and SPECT imaging can accelerate the drug development process by revealing early information regarding drug effectiveness and safety for both research and regulatory purposes.

Receptive Field Modeling

Brian Blais
Department of Science and Technology, Bryant University, Smithfield, RI, USA
Institute for Brain and Neural Systems, Brown University, Providence, RI, USA

Synonyms

Neural Development; RF Modeling

Definition

The mathematical modeling of properties of *sensory* neurons, specifically relating to the patterns that elicit strong neuronal responses.

Detailed Description

The term *receptive field* (RF) refers to any of the following, depending on the context:

1. The *sensory area* over which sensory neurons give strong responses (e.g., portion of the visual field for visual neurons, frequency range for auditory neurons, etc.)
2. The *input patterns* that elicit those strong responses
3. The pattern of strong and weak *synaptic strengths* that results in the strong responses to the specific patterns
4. The *spatiotemporal* response properties of the sensory neurons, often referred to as a spatiotemporal receptive field

Modeling refers to the *mathematical* modeling of the response properties of the neuron or the development of the pattern of synaptic strengths and/or the neural dynamics that give rise to those response properties. Thus, the models are often specified as a set of differential equations for the parameters of the model, typically the synaptic weights, and include the activities for both the inputs to and outputs from the neurons.

Sensory neurons include neurons organized in a hierarchical structure (shown in Fig. 1 for visual neurons). For the visual system, this includes neurons in the retina, lateral geniculate nucleus (LGN), and visual cortex. For the auditory system it includes the cells in the cochlea, medial geniculate nucleus (MGN), other subcortical areas, and primary auditory cortex. Thus, the concepts motivating receptive field developmental models in one sensory modality can often be applied directly to another sensory modality.

Receptive Field

Modeling, Fig. 1 Visual architecture. Shown is the visual field, approximated here as a two-dimensional projection, to left and right retinal cells. These left and right retinal cells project to the left and right LGN cells, respectively, and finally to a single cortical cell. The *receptive field* can refer either to the area in the visual field (labeled with the yellow circles) that the cell can see or the distribution of the synaptic weights that yield responses within the visual field (labeled with large blue circles)

Kinds of Models

Models of receptive field activity and development fall into a few categories:

1. Mathematical approximation to the response properties of the neurons. In these models, a mathematical form is proposed that matches the response properties of the neurons.
2. Development of the receptive field through an optimization process. In these models, the connection weights (i.e., synaptic strengths) or other neuronal parameters are adjusted to optimize a proposed objective function. Objective functions include measures of sparsity (Rao et al. 2002), independence (Hyvärinen et al. 2001b), and selectivity (Cooper et al. 2004; Blais and Cooper 2008).
3. Detailed models of the *spiking* behavior of neurons. These models include the stochastic nature of the inputs and outputs and often are motivated by concepts in molecular biology

(Yeung et al. 2004; Smith and Lewicki 2006; Gjorgjieva et al. 2011).

Mathematical Approximations

Mathematical Approximation for Retinal and LGN Receptive Fields

Both retinal neurons and neurons in the LGN have what is referred to as a center-surround receptive field. A spot of light in the center of the visual area elicits a strong response, a uniform illumination over the entire area elicits a weak response, and light illuminating only the area around the center elicits a suppressed response (Alonso and Chen 2009).

The typical functional form used for retinal responses is the so-called center-surround form, mathematically expressed as a difference of Gaussians, depicted graphically in Fig. 2 (Enroth-Cugell and Robson 1966; Rodieck 1965).

LGN cells typically have response properties similar to those of retinal ganglion cells and thus

Receptive Field Modeling, Fig. 2 Representations of receptive fields. Shown are the (a) center-surround retinal/LGN receptive fields and the (b) Gabor-like visual cortical receptive fields

can be modeled with a spatial difference of Gaussians. Temporally, the LGN can be described approximately in terms of lagged and non-lagged populations, differing in their phase lags (Saul and Humphrey 1990). More details reveal that a distribution of delays exists (Wolfe and Palmer 1998).

Mathematical Approximation for Visual Cortical Receptive Fields

So-called simple cells in the visual cortex respond to *bars of light* of a particular orientation in their receptive field and have *binocular* receptive fields (Hubel and Wiesel 1962). The cortical responses can be approximated with a Gabor function (Jones and Palmer 1987), which is a 2D circular Gaussian multiplied by a sinusoidal plane wave (see Fig. 2). Other forms can also be used and may perhaps fit to

the data better but qualitatively have the same form (Stork and Wilson 1990; Rust et al. 2005).

Nonlinear combinations of these simple responses are an approximation to some of the more complex receptive fields of visual neurons (Finn and Ferster 2007; Adelson and Bergen 1985).

Mathematical Approximation for Auditory Cortical Receptive Fields

In auditory cortex, there is considerably more diversity of responses, and thus the response properties are not easily summarized by a simple mathematical approximation. Many of these cells are *frequency tuned*, responding to a narrow band of sound frequencies, but others respond strongly to transient sounds or are intensity tuned (Bear et al. 2007).

Development of Receptive Fields

The essential idea behind models of receptive field development is the learning of structure in the input environment through some form of statistical optimization. Differences between the methods proposed to describe receptive field development can arise from both the particular optimization performed and the statistics of the input environment used to develop the neuronal responses. Common examples of statistical optimization used in receptive field modeling are:

1. Bienenstock, Cooper, Munro (BCM) – maximizing statistical bimodality in the distribution of cortical responses (Bienenstock et al. 1982; Blais et al. 1998; Cooper et al. 2004).
2. Independent Component Analysis (ICA) – maximizing independence between input patterns (van Hateren and Ruderman 1998; Hyvärinen et al. 2001b)
3. Sparse Coding – maximizing sparsity in the distribution of cortical responses (Olshausen and Field 1996; Rao et al. 2002).

Note that these differences are not always clearly distinguishable, such as using ICA to do sparse coding. Further, some of the proposed methods have not just their receptive fields tested by experimental observations but also the underlying mechanisms explored in detail. For a nice survey of the comparison between theory and experiment for the BCM learning rule, see Cooper and Bear 2012.

Examples of input environments used with these methods include:

1. Retinal waves for retinal and LGN development (Wong 1999)
2. Natural image input for the development of orientation selective and binocular receptive fields (Blais et al. 1998; Cooper et al. 2004; Hyvärinen et al. 2009).
3. Natural image movies for the development of spatiotemporal receptive fields in visual cortex, resulting in direction selectivity (Hyvärinen et al. 2001b; Blais et al. 2000; Cooper et al. 2004).

4. Natural sounds for the development of frequency-temporal receptive fields in auditory cortex (Smith and Lewicki 2006; Saxe et al. 2011).

A sample of visual cortical receptive fields in natural image input in a model of the visual system is shown in Fig. 3.

Organization of Receptive Fields

Beyond the development of selectivity properties of the receptive fields (e.g., orientation, direction, spatial frequency, temporal frequency, etc.), some models attempt to also capture the distribution and arrangement of these receptive field properties in the cortex. Invariably this includes models of the *interaction* between neurons during development. Thus, models include self-organizing maps (Kohonen 2001), short- and long-range lateral connections (Shouval et al. 2000), topographic ICA (Hyvärinen et al. 2001a), and deep belief networks (Lee et al. 2007).

Receptive Field Modeling, Fig. 3 Sample receptive fields developed from natural image input, using the BCM learning rule (Bienenstock et al. 1982), a method that modifies the synaptic strengths to maximize statistical bimodality in the distribution of cortical responses. Shown are the synaptic values with *white* and *black* denoting strong and weak (or negative/inhibitory) connections, respectively

For a good review in the visual system, see Hyvärinen (2010).

Other Sensory Neurons

Less work has been done in the area of modeling other sensory areas, such as somatosensory (i.e., touch) and olfactory (i.e., smell) systems. Some progress has been made using sparse coding to develop somatosensory receptive fields (Saxe et al. 2011). Part of the challenge in the olfactory system is that the *field* of odor parameters is not well understood, so even the space over which one could establish a receptive field is not well defined.

Definition

Reconstruction of neural circuits using large volumes of electron microscopy (EM) data is essential for understanding the function and dysfunction of the nervous system. The reconstruction task involves the geometric tracing of each neurite and the identification of the interconnections between neurons in order to obtain a complete wiring diagram of the nervous system, known as the connectome.

Detailed Description

To reconstruct the connectome that reveals synaptic connections, the tissue has to be imaged at a

sufficiently high resolution. EM can provide image data at nanometer scale and has been a key source of 3D imaging data for the study of neuroanatomy for years (Macagno et al. 1979; Stevens et al. 1980). For example, the entire nervous system (302 neurons and over 7,000 synaptic connections) of the nematode *Caenorhabditis elegans* was reconstructed (White et al. 1986) using serial section transmission electron microscopy (ssTEM).

Breakthroughs in high-throughput and high-resolution three-dimensional EM imaging instruments have made the acquisition of unprecedented amounts of biological data possible. See ► “Physical Sectioning Microscopy.” These techniques have enabled the acquisition of large-scale data sets and have opened new roads for the connectomic research. However, data produced by these instruments pose significant challenges due to the amount and complexity of information. For example, an SBFSEM data set at a resolution of $10 \times 10 \times 50$ nm, sectioning a $200^3 \mu\text{m}^3$ sample tissue, results in a data set of 1.6×10^{12} voxels (Denk and Horstmann 2004). In Fig. 1, we can see two EM (ssTEM and SBFSEM) image stacks and their sample images. Manual reconstruction of the *C. elegans* connectome took more than a decade. To reconstruct more complex neural circuits, such as *Drosophila* or mouse brains, automation of the reconstruction process is a necessity. One of the main steps in EM reconstruction is image segmentation. It is to partition an image into disjoint regions, each of which shares common characteristics. For EM data, segmentation groups voxels into different sets that represent distinct neurons (Chklovskii et al. 2010), which is a fundamental step toward a full analysis of neuronal morphological models. Such a task poses unique challenges because of the inevitable staining noise, incomplete boundaries, and inhomogeneous staining intensities that can make segmentation and subsequent 3D reconstruction and visualization difficult. Numerous methods have been proposed to automate EM segmentation. They can be grouped into three categories: machine learning-based, semiautomated, and crowdsourcing-based approaches.

Reconstruction, Electron Microscopy, Fig. 1 Sample EM images and image stacks. (a) A sample ssTEM image having a size of 512×512 from a data set of *Drosophila* first-instar larva ventral nerve cord (VNC). The resolution is $4 \times 4 \times 50$ nm/voxel. (b) A publicly available ssTEM data set provided by Cardona et al. 2010. (c) A sample

SBFSEM image having a size of 631×539 from a data set of larval zebrafish tectum. (d) An SBFSEM image stack. Note that cells in both the ssTEM and the SBFSEM images are densely packed. (Courtesy of Stephen J. Smith, Stanford University)

Reconstruction, Electron Microscopy, Fig. 2 Measured warping error of a segmentation against the ground truth. (a) A sample EM image. (b) Manually annotated ground truth. (c) A segmentation to be

evaluated. (d) Measured warping error. In this case, two topological errors, a merge (blue circle, right) and a split (red circle, left), occur due to the boundary ambiguity in the original image

Reconstruction Approaches

Machine learning-based approaches for EM reconstruction involve training classifiers that can perform the segmentation task. The basic idea of machine learning approaches is that humans provide a set of positive and negative examples (i.e., training data) to a machine learning algorithm so that it can learn to perform classification on unseen data. In EM reconstruction, a machine can be trained to learn to distinguish cellular membranes from other objects given manually annotated ground truth. During learning, using the given training examples, the machine learns to perform the classification task by optimizing its parameters through minimization of a cost function, which, for example, can be the measure of disagreements between machine

generated segmentations and manual annotations. After learning, a machine learning algorithm can segment new EM data that was not included in the training. 3D convolutional neural networks, trained to minimize topological errors, have been proven to be an effective method because EM data contains detailed connectivity of neurons and the topological correctness of the reconstruction is critical in EM analysis (Jain et al. 2010). Topological errors can be measured by a *warping error* metric, which is designed specifically for EM data. Figure 2 illustrates the importance of topology. Figure 2a shows part of an ssTEM image and Fig. 2b its ground truth. Compared to the ground truth, the segmentation in Fig. 2c contains two topological errors, one merge and one split, as shown in Fig. 2d. Classifiers based on random forests (Andres et al. 2008), artificial neural

networks (Jurrus et al. 2010), and support vector machine (SVM) (Lucchi et al. 2010) are also widely used in EM reconstruction.

In addition to training a machine to perform membrane detection at the pixel level, another trend is to have a machine actively learning to perform agglomerative segmentation through superpixels (Nunez-Iglesias et al. 2013). Superpixels are small regions having common characteristics. In the process of region agglomeration, the machine determines whether or not two adjacent superpixels should be merged based on a merging criterion. The advantage of performing the segmentation at the superpixel level is that richer features can be incorporated in the learning algorithm, thus improving the segmentation accuracy.

Semiautomated approaches have also gained much attention because of the complexity of EM images. These approaches take as input user-specified seed points or neuronal contours and trace them through successive 2D cross sections to build 3D anatomical structures. The 2D segmentation is commonly posed as an energy minimization problem. To follow the neuronal processes, the 2D contour is propagated from a slice to the next. Such information can serve as a geometric constraint and can be incorporated in a Markov Random Field (MRF) energy functional while delineating the neuronal boundaries of an image (Yang and Choe 2009). Figure 3a–c shows the tracked 2D contours on the selected images using such an approach, and Fig. 3d shows the reconstruction results.

Besides following neuronal processes from user-specified seed points or contours, another semiautomated method employs a multistage approach: 2D segmentation, 3D linkage, and proofreading. The first stage is to segment each 2D section separately, the second is to link the segmentations between adjacent slices to reconstruct 3D neuronal structures, and finally, proofreading ensures the correctness of the reconstruction (Chklovskii et al. 2010). In this reconstruction pipeline, proofreading is a step that requires manually correcting reconstruction errors. Interactive systems, such as Raveler (Chklovskii et al. 2010) and Mojo (Knowles-Barley et al. 2013), are used for such a task. The proofreading systems provide two basic editing operations: merge and split. The merge operation allows the user to connect two disjoint regions, and the split operation allows the user to divide a region into subregions. To reduce annotation time, Mojo uses sparse user scribbles to correct topological errors.

To deal with extremely large volumes of EM data, crowdsourcing-based approaches are used. They employ large number of citizen scientists with the goal of reconstructing a complete connectome. EyeWire, designed as an online game and launched in 2012, aims at mapping the neuron connections in the retina (<http://eyewire.org>). In EyeWire, each player is presented by a small EM volume, and the task is to trace the neurons. Combining the results from all the users builds the complete reconstruction.

Reconstruction, Electron Microscopy, Fig. 3 Tracked and segmented 2D contours on selected image slices. The user manually delineates the boundaries of the regions on the first image (a), and the algorithm tracks and segments

the selected regions in the subsequent images (b)–(c). (d) Partly reconstructed 3D structures, where part of a neuron can be seen (Adapted from Yang 2011)

Reconstruction Software Packages

Manual tracing is a labor-intensive task and many reconstruction software packages have been developed to aid in manual reconstruction. These software packages provide user interfaces to assist users in processing, analyzing, and visualizing serial EM images. This leads to reduction in annotation time. For EM reconstruction, the software packages include tools for users to align image volumes, trace neurons, and visualize 3D reconstructions. *Reconstruct* is one such software package for large volumes of serial EM images (Fiala 2005). Most packages use volume annotation method to reconstruct neuronal processes. This requires correct delineation of the cell boundary. Skeleton annotation, in which the user places markers at the center of the neurons, takes less human effort. KNOSSOS (Briggman et al. 2011; Helmstaedter et al. 2011) provides a skeletonization mode to make manual tracing more efficient. In combination with a machine learning approach for neuronal membrane detection, crowdsourced manual annotation using KNOSSOS has mapped the mouse inner plexiform layer of 950 neurons in the retina (Helmstaedter et al. 2013). Other software packages, such as TrakEM2 (Cardona et al. 2012) and NeRV (Jurrus et al. 2013), also have been developed for manual EM reconstruction. Different from the software packages that reconstruct neural circuits from raw EM images, VolRoverN (Edwards et al. 2013) takes as input existing contour tracings produced by other software tools and focuses on accurate surface reconstructions. Models of these surface reconstructions can be used for simulation of neuronal dynamics. Identification of the presynaptic and postsynaptic connectivity is crucial in connectomic research. Elegance (Xu et al. 2013) provides tools for synapse annotation and produces a connectivity matrix, including synaptic strengths, for analysis of the network function.

Definition

Reconstruction algorithms are used to build a geometric model of neurons, describing their

morphology, from two-dimensional and three-dimensional images. Validation methods are used to determine the accuracy of the resulting models. Both reconstruction and validation are active areas of research, where proposed algorithms must address several complex problems, including (a) the use of a wide range of imaging modalities used to collect data, (b) the complex topological structure of interconnected branches within the neurons, and (c) automation for large data sets. Several methods have been proposed for addressing these issues; however, current reconstruction algorithms can be broadly placed into four categories: semiautomated software packages, local exploration, global processing, and crowdsourcing-based approaches.

Detailed Description

Neuronal reconstructions provide geometric representations of cell and network morphology that can be used to perform quantitative analysis and simulation (e.g., of multicompartmental models). Depending on the features required, this representation can take the form of either a detailed three-dimensional surface or a cylinder-based representation (Ascoli et al. 2001). Surface representations are generally created from high-resolution serial electron microscopy (EM) images and used to analyze cellular ultrastructure, including spine shape and receptor density. Cylinder-based representations are more commonly used to describe the morphology of dendritic trees and axonal arbors where each segment in the processes is fitted with a cylinder. The multicompartmental models used in computational simulations of neurophysiology (e.g., using NEURON or GENESIS (Bower and Beeman 1998; Carnevale and Hines 2009)) are generally created from cylinder-based representations.

Reconstruction

While a significant amount of research has been directed toward automated methods, semi-automated techniques are still widely used.

These methods focus on creating optimized user interfaces for labeling cellular structures and tracing neuronal processes. These methods are most commonly used in serial EM, due to the complexity of these images. Traditional methods rely on a user specifying neuronal boundaries in a 2D cross section of a 3D data set (Fiala 2005), while automated methods are also actively being developed (Mishchenko et al. 2010). Segmented regions are then used to build 3D explicit model of the cell surface. For large-scale data sets, faster reconstruction can be achieved by specifying the centerlines of cellular processes in order to build a cylinder-based representation (Helmstaedter et al. 2011).

Alternatively, local exploration relies on traversing a process starting from user-specified seed points. For each seed point, the local region around the process is analyzed to determine its size and trajectory. This allows the neuronal processes to be traced outward and limits the amount of image data to the relevant regions near the neuron (Luisi et al. 2011; Meijering 2010). This provides a significant computational advantage for sparse data sets, where individual neurons are labeled in isolation. These techniques usually create a cylinder-based representation of the cell. Localized exploration is among the most popular methods for reconstructing light microscopy data (Halavi et al. 2012).

The development of fully automated global reconstruction techniques is an active area of research. A significant amount of work has been proposed regarding the use of supervised machine learning to perform segmentation, particularly in serial EM data sets (Jain et al. 2010b).

Finally, crowdsourcing has proven to be quite effective for large-scale, complete reconstruction (Giuly et al. 2013; Seung and Burnes 2012). In this approach, the reconstruction task is broken down into tiny subtasks that are distributed to a large population of volunteer users who mechanically solve the subtasks typically posed as an entertaining online game. Pooling together the solutions to the subtasks from the users produces the desired reconstruction.

Validation

Validation methods are used to determine the robustness of segmentation algorithms by comparing automated results to a known ground truth. These methods are useful for comparing reconstruction algorithms on known data sets, as well as training new classifiers using supervised learning techniques. Quantitative validation of automated reconstructions is a particularly challenging problem, due to the unique structure of neurons and the explicit representation of most models.

Implicit representations of the neuronal model can be constructed and compared to a ground truth using cluster analysis metrics, including the Rand error and variation of information (Meila 2003). Initial efforts extended these existing methods to neuronal models using *warping error* (Jain et al. 2010a). This implicit metric is used to compare segmentation results in serial slices of EM data and is particularly sensitive to topological errors, which can significantly affect connectivity between multiple neurons in serial EM images.

Explicit validation metrics have also been proposed for comparing cylinder-based models more commonly used for whole-neuron or multiple-neuron reconstructions. These methods extend metrics used for surface comparisons, such as quadric error metrics and the Hausdorff distance (Luebke et al. 2002). One of the first techniques to directly address the problem of large-scale validation of neuron tracing is the DIADEM metric, which was used to quantify the performance of segmentation algorithms submitted to the DIADEM Challenge (Liu 2011). This method first identifies points where the neuronal process branches or terminates, creating a mapping between these nodes in the ground truth and test case. The lengths of segments connecting these points are then computed and compared.

While the DIADEM metric can be used to effectively compare the topological structure of neuronal trees, the application of validation methods to connectomics research generally requires the comparison of connected networks, which do not necessarily exhibit treelike properties. In addition, comparing the lengths of segments between branch points does not

necessarily guarantee that a process exhibits the correct shape. A more complete solution to this problem requires a thorough comparison of the network shape and connectivity (Mayerich et al. 2012). This converges to a graph isomorphism problem, which is known to be NP-complete.

Finally, synthetic neuronal morphology generator tools such as TREES toolbox, NETMORPH, neuroConstruct (Gleeson et al. 2007), NeuGen (Eberhard et al. 2006), and I-Neuron (see Cuntz et al. 2011 for a review) can be used to generate digital phantoms for automated ground-truth generation and validation.

Recurrent Brain-Computer Interfaces

Andrew Jackson
Institute of Neuroscience, Newcastle University,
Newcastle-upon-Tyne, UK

Synonyms

[Bidirectional brain-machine interface](#); [Brain-machine-brain interface](#); [Closed-loop neuroprosthesis](#)

Definition

A recurrent brain-computer interface (or rBCI) exchanges information directly with the nervous system in a bidirectional manner, bypassing sensory and motor modalities. These devices can both sense neural activity (usually by amplifying and processing electrical potentials) and influence it (by electrical or other stimulation methods). Applications include neuroprostheses to replace lost function and neuromodulation devices to renormalize function following neurological injury or disease.

Detailed Description

History

The earliest recurrent brain-computer interface was the “stimoceiver” built and used by the Spanish physiologist Jose Delgado (Delgado et al. 1968; Horgan 2005) at Yale University. He believed that this wireless device, which combined electrical recording and stimulation of the brain, could be used for treatment of neurological conditions including depression, schizophrenia, and epilepsy. About 25 patients were implanted with the device from 1952 to 1974 after which Delgado returned to Spain in part due to controversy over potentially unethical applications of “mind control.” Around the same time Giles Brindley, working at the MRC Neurological Prostheses Unit in London, proposed using electrical activity recorded from the motor cortex to control an implanted stimulator and thus restore movement to spinal cord-injured patients (Craggs 1975). The clinical success of deep brain stimulation as well as recent advances in brain-machine interface technologies including high-density electrode implants and low-power microelectronics has led to renewed interest in rBCI applications in recent years (e.g., Rouse et al. 2011; Morrell 2011).

System Components

Recurrent brain-computer interfaces generally comprise three components (Fig. 1). A *sensor*

Recurrent Brain-Computer Interfaces, Fig. 1 Components of a recurrent brain-computer interface

transduces neural activity, usually by recording electrical signals on one or more electrodes positioned on the scalp or inside the brain. A *processor* detects relevant features in the recorded signals, for example, action potential discharges relating to motor intentions, the phase and amplitude of ongoing neural oscillations, or abnormal brain events such as seizures. These features are used to determine the timing, frequency, and/or intensity of a *stimulator* which delivers signals back to the nervous system. Since information travels in a loop from the brain to the device and back again, such an arrangement is often called “closed-loop” neurostimulation. Note, however, that the term “closed loop” can also be used to describe the operation of a brain-computer interface under conditions where feedback is provided to the user through visual or other sensory modalities. A system in which signals from the motor cortex control the movement of an avatar and feedback is provided through stimulation of the sensory cortex has been described as a brain-machine-brain interface (O’Doherty et al. 2011). rBCIs may be implemented by noninvasive technologies such as electroencephalography and transcranial magnetic stimulation or invasive approaches using implanted microelectrodes. If the processor is implemented in wearable or implanted electronics, an rBCI may operate autonomously delivering closed-loop stimulation continuously without the need for external communication. One technical problem with rBCIs that use electrical stimulation is the contamination of recordings by stimulus artifacts if the recording is adjacent to where stimulation is delivered. Therefore, other nonelectrical means for stimulating neurons such

as optogenetic techniques that use light-sensitive ion channels may prove particularly advantageous for rBCIs (Witt et al. 2013).

Theory of Operation

At its simplest, an rBCI can act as an artificial connection between two parts of the nervous system which may replace or augment a physiological connection (e.g., between the brain and the spinal cord). In more sophisticated implementations, additional processing may be performed between the input and the output so as to perform some useful computation and potentially replace a lost cognitive function (Berger et al. 2005). Long-term operation of an rBCI may result in several secondary changes as a result of known neuroplasticity mechanisms. First, operant conditioning may optimize upstream inputs into the device so as to produce a beneficial or rewarding output (e.g., if stimulation is delivered to a reward center). Second, associative or Hebbian plasticity mechanisms such as spike timing-dependent plasticity may strengthen physiological connections between recording and stimulation sites (Jackson et al. 2006). Third, stimulus-induced activity may strengthen downstream connectivity through long-term potentiation. It has been argued that these three changes may act synergistically to retrain injured pathways during rehabilitation (Jackson and Zimmermann 2012).

Alternatively, the operation of an rBCI may be considered in the framework of dynamical systems. Through recurrent connections between the brain and device, the resulting coupled system may exhibit different attractor dynamics, for example, undesired oscillatory states may become unstable. Such an approach may have application to disorders characterized by abnormal network dynamics, for example, Parkinson's disease and epilepsy (Marceglia et al. 2007; Witt et al. 2013).

Echo state networks; Liquid computing; Liquid state machines; State-dependent networks; Temporal recurrent neural networks

Definition

Reservoir computing (RC) is a general concept for computation and learning on temporal input streams with dynamical systems. Time can either be continuous or discrete. We will here use continuous time for the general definition. An input-driven dynamical system (the *reservoir*) provides a nonlinearly transformed and temporally integrated representation of the input stream in terms of its internal state. This representation is utilized by a *readout* which maps internal states to outputs of the system. The output of the readout can be fed back into the reservoir. The reservoir is typically a recurrent neural network, but other dynamical systems have been employed in the RC spirit recently. The readout function is adapted through some learning procedure. Originally, this training was supervised and the reservoir was not adapted. Today, many extensions of the original idea include unsupervised or reward-based readout training and unsupervised reservoir adaptation. This is in contrast to traditional recurrent neural network training where the whole network is trained in a supervised manner.

More formally, a *RC system* computes a mapping from a K -dimensional input stream $\mathbf{u}(\cdot)$ to a L -dimensional output stream $\mathbf{y}(\cdot)$. It consists of an N -dimensional dynamical system with internal state (*reservoir state*) $\mathbf{x}(t)$ and a memoryless readout function f . The reservoir state at time t , $\mathbf{x}(t)$, depends on the preceding inputs $\mathbf{u}(s)$ for $s \leq t$. In mathematical terms, the state $\mathbf{x}(t)$ is the current output of some operator or filter $\mathcal{F}$ that maps the functions $\mathbf{u}$ onto functions $\mathbf{x}$ (note that in the case of readout feedback, the dependence of $\mathbf{x}$ on the output $\mathbf{y}$ can be incorporated in the filter $\mathcal{F}$). The memoryless readout function f provides a mapping from the vector $\mathbf{x}(t)$ to the output $\mathbf{y}(t)$.

Detailed Description

The theoretical concept of RC was introduced independently in the context of theoretical/computational neuroscience as liquid state machines (LSMs; Maass et al. 2002) and in the context of

recurrent artificial neural networks as echo state networks (ESNs; Jaeger 2001). Earlier implementations of the idea are temporal recurrent neural networks (Dominey 1995) and state-dependent networks (Buonomano and Merzenich 1995).

Liquid State Machines

In LSMs, the reservoir is called the *liquid* and the reservoir state is the *liquid state*. The liquid is a recurrent network of spiking neurons. The liquid state at time t , $\mathbf{x}(t)$, is obtained by filtering of the network spikes. Usually, a linear filter with exponential decay is used, mimicking the membrane potential of cortical readout neurons.

Typically, synaptic connections involve short-term plasticity such as short-term facilitation and short-term depression. The prolonged time constants of these processes provide additional temporal integration power. Each readout unit computes a pseudo-linear function of the system state

$$\mathbf{y}(t) = g(\mathbf{W}^{\text{out}}\mathbf{x}(t) + \mathbf{b}). \quad (1)$$

Here, the output activation function (usually the identity or a sigmoid) g is applied component-wise, $\mathbf{W}^{\text{out}}$ is the $L \times N$ matrix of output weights, and $\mathbf{b}$ is the L -dimensional vector of bias values. Training proceeds as in ESNs; see below.

LSMs were introduced as a model for computation and learning in cortical microcircuits. One major incentive was to explain how complex but stereotypic cortical microcircuits can process spatiotemporal information in order to perform a wide spectrum of tasks. In this context, the cortical microcircuit is seen as the liquid, and projection neurons in layers 2/3 and 5 implement the readout neurons. The LSM model possesses a number of advantageous features that were in contrast to most other models for cortical computation at that time:

- LSMs map temporal input streams onto temporal output streams instead of static patterns.

- LSMs perform anytime computations, i.e., the result of a computation can be probed at any time, with usually better results as more information is integrated in the liquid over time.
- Diverse network components (diverse types of neurons and diverse dynamics of synaptic connections) as found in cortical circuits in general improve the computational power of LSMs.
- The LSM hypothesis circumvents the problem of neural coding – circuit states are good if they are useful for the task.
- No precise circuitry is needed in order to perform useful computations, instead a specific functionality is acquired through learning. In particular, the liquid is usually a randomly connected spiking neural network.

2. Run the network on the training input $\mathbf{u}$ and collect the reservoir states $\mathbf{x}(1), \dots, \mathbf{x}(T)$. If feedback is required, use (possibly a noisy version of) the target output $\mathbf{y}^*(1), \dots, \mathbf{y}^*(T)$ for the feedback in Eq. 2. This procedure is called *teacher forcing*.
3. Compute the optimal output weights $\mathbf{W}^{\text{out}}$.

For a linear readout, the readout weights $\mathbf{W}^{\text{out}}$ are typically determined by regularized least squares. Various variants for readout training as well as for adaptation of the reservoir have been proposed (Lukoševičius and Jaeger 2009). Recently, it has been shown that supervised learning can often be replaced by reward-based learning (Hoerzer et al. 2012).

Echo State Networks

In an ESN, the reservoir is a recurrent artificial neural network consisting of randomly connected neurons. Consider an ESN with N reservoir neurons, a K -dimensional input $\mathbf{u}$, and L outputs $\mathbf{y}$. The reservoir state $\mathbf{x}$ of a standard discrete-time reservoir in an ESN evolves according to

$$\mathbf{x}(t+1) = \sigma(\mathbf{W}\mathbf{x}(t) + \mathbf{W}^{\text{in}}\mathbf{u}(t+1) + \mathbf{W}^{\text{fb}}\mathbf{y}(t)), \quad (2)$$

where σ is a sigmoid function (usually the tanh), $\mathbf{W}$ is the $N \times N$ matrix of recurrent weights, $\mathbf{W}^{\text{in}}$ is the $N \times K$ matrix of weights from input units to reservoir neurons, and $\mathbf{W}^{\text{fb}}$ is the $N \times L$ matrix of weights from output units to reservoir neurons. Some tasks may not require feedback from the readout units to the reservoir. In ESNs, the readout is a pseudo-linear function of the *extended system state*, that is, the vector $(x_1(t), \dots, x_N(t), u_1(t), \dots, u_K(t))^T$.

For supervised training, a training set is given that consists of a sequence of inputs $\mathbf{u}(1), \mathbf{u}(2), \dots, \mathbf{u}(T)$ and target outputs $\mathbf{y}^*(1), \mathbf{y}^*(2), \dots, \mathbf{y}^*(T)$. Training proceeds in the following steps (Lukoševičius et al. 2012):

1. Generate a random reservoir by choosing weight matrices $\mathbf{W}$, $\mathbf{W}^{\text{in}}$, and $\mathbf{W}^{\text{fb}}$.

Theory

Maass et al. (2002) presented a universal approximation theorem for LSMs without readout feedback based on two properties:

- The *separation property* addresses the amount of separation between the trajectories of liquid states that are caused by two different input streams.
- The *approximation property* addresses the capability of the readout to distinguish and transform different liquid states into given target outputs.

The theorem states that any time-invariant fading memory filter can be approximated to any degree of precision by an LSM if the liquid possesses the separation property and if the class of functions from which the readout map is drawn satisfies the approximation property. Informally, a filter has fading memory if the most significant bits of its current output depend just on the most significant bits of the values of its input function from some finite time window into the past (Boyd and Chua 1985).

The computational power of an LSM increases significantly if readout feedback is incorporated. In this case (and in the absence of noise), it can carry out any conceivable digital or analog

computation on time-varying inputs (Maass et al. 2007).

Not every reservoir can be used for reservoir computing. In the case of an ESN, the reservoir needs to have the *echo state property* (ESP; Jaeger 2001). Intuitively, the ESP states that the reservoir will asymptotically wash out any information from initial conditions. An easy to check sufficient condition for the ESP can be derived for tanh reservoir neurons. If the largest singular value of W is below 1, then the reservoir has the ESP. On the other hand, if the spectral radius of W is above 1, then the network does not have the ESP for zero input. These conditions imply that in order to satisfy the ESP, one simply has to scale the network weights.

Applications

LSMs have become an important theoretical concept for understanding complex brain networks (Buonomano and Maass 2009; Destexhe and Contreras 2006; Rigotti et al. 2013; Nikolic et al. 2009).

The dynamics of recurrent spiking networks is in general harder to tune because of a much sharper phase transition between the ordered and chaotic regime (Buesing et al. 2010). Therefore, ESNs are often preferred over LSMs in engineering applications (see, e.g., Lukoševičius et al. (2012) for a review). Although the general emphasis is on engineering, ESNs were also used to model biological neuronal networks.

Temporal recurrent networks were introduced by Peter F. Dominey (1995) to model corticostriatal circuits. Dominey was probably the first who explicitly spelled out the RC principle. State-dependent networks were introduced by Buonomano and Merzenich (1995) to model temporal processing in cortical circuits.

RC applications outside the field of neural networks include analog electronics, atomic switch networks based on nanowires, optoelectronic, and optical systems (see Lukoševičius et al. (2012)).

Simplified conductance-based models

Definition

Reduced morphology models are simplified computational models obtained by collapsing the dendritic tree of a detailed neuron model, in such a way to preserve as much as possible the original membrane dynamics.

Detailed Description

Morphologically detailed neuron models are based on 3D anatomical cell reconstructions and describe how the spatial dendritic structure of a neuron together with the kinetic properties and distributions of ion channels and synaptic inputs contributes to the dynamics and functionality of a neuron. These *compartmental neuron models* are usually composed of hundreds of dendritic branches (Fig. 1) with nonlinear membrane properties.

Mathematically, they are described by thousands of coupled nonlinear partial and ordinary differential equations. The high dimensionality and intricate system structure impede the mathematical understanding of their emergent properties, and detailed investigations of the parameter space and simulations, using this kind of implementation in large networks, are rarely carried out because the computational cost dramatically

Reduced Morphology Models, Fig. 1 Typical 3D reconstruction of a hippocampal CA1 pyramidal neuron (a) and of a Purkinje cell (b). Both reconstructions were downloaded from the public neuromorpho.org database (cell c70863 and e4cb2a2, respectively)

increases with network size. These problems have prompted the need for a suitable reduction of a realistic neuron into a much simpler computational model, since the individual neuron dynamics and its role within a network are a fundamental problem for *Computational Neuroscience*. The design of a reduction method requires a delicate balance between incorporating sufficient details to account for the complex single-cell dynamics and reducing this complexity in such a way to implement a computationally efficient model. Systematic approaches to build simplified models with electric behavior equivalent to a detailed representation started with the concept of *equivalent cylinder* introduced by Rall (Rall 1959, 1964; Rall and Rinzel 1973; Rinzel and Rall 1974; Rall et al. 1995). The pioneering idea of Rall consisted in collapsing an idealized branching dendritic tree into a mathematically equivalent single cylinder with the same total membrane area and electrotonic structure. However, this method requires specific mathematical assumptions: (i) all dendrites must end at the same electrotonic distance from soma; (ii) the specific membrane resistance R_m and capacitance C_m , as well as the specific axial internal resistivity R_i , must be uniform throughout the structure; and (iii) branch point diameter must follow the $3/2$

power rule. These conditions are not satisfied for the great majority of real neurons, and, moreover, the method does not apply to cells with non-uniform active kinetic and synaptic properties.

Building up on Rall's seminal works, various alternative reduction methods have been suggested. Here we will discuss the two main approaches: theoretical or heuristic methods.

Theoretical Methods

In these cases, the reduction of a dendritic neuron tree into an *equivalent branched or unbranched cable* (i.e., a single or multicylinders with variable diameters) can be mathematically derived from theoretical grounds.

Clements and Redman (Clements 1986; Clements and Redman 1989) introduced a method to collapse a dendritic tree into an unbranched electrotonic cable in which the compartments can have unequal diameters. This method assumes that *all points on the dendritic tree at a given electrotonic distance from the soma will be at the same potential at all times*. The method thus cannot be applied to real neuron cells with nonuniform active kinetic and synaptic properties.

In Schierwagen (1994), the reduction to an equivalent cable can be derived only for passive dendritic trees fulfilling certain symmetry conditions.

Ohme and Schierwagen (1998), extending Rall's 3/2 power rule, developed a mathematical method to reduce branching neuronal trees with active ion channels into an equivalent cable model (see Fig. 2).

However, their main result (*Equivalent Cable Theorem*) applies only to ideal neuronal trees fulfilling special geometrical and electrical conditions such as:

1. For all dendritic segments, the membrane time constants must be uniform and independent of the segments.
2. All terminal nodes must have the same electrotonic distance from the soma.

3. The voltage functions are equal in all parallel segment domains (see the grey-labelled regions in Fig. 3).
4. All segments must be of the same geometric type, and nodes must satisfy an additional condition (Eq. 14 in Ohme and Schierwagen 1998).
5. At each node all (nonvanishing) current functions must be distributed among all locations at the same electrotonic distance from the soma corresponding to the weights of their parent segments.

These conditions prevent the use of the method for real neurons. An additional adaptation of specific cell parameters of the reduced cable leads to a procedure that is computationally more expensive than the heuristic method proposed by Bush and Sejnowski (1993; see next section).

Finally, in Evans (2000), the exact solution of a multiple equivalent cylinder cable model for passive neurones was derived. Relaxing certain symmetry conditions necessary for the Rall equivalent cylinder reduction, the model consists of one or more tapering equivalent cylinders (belonging to a class of six specific forms) connected to a uniformly polarized soma. Following this approach, in Evans (2005), an analytical solution of the cable equation with synaptic reversal potentials for a pair of electrotonically coupled passive neurons was considered. In this approach, the synaptic inputs were modeled as a conductance change.

Heuristic Reduction Methods

Empirical methods to create reduced models follow two main approaches: (i) implementing the generic electrophysiological properties of a given neuron population with single- or multi-compartment conductance-based models and (ii) devising rules to reduce a full morphological and biophysical model into a simpler one.

In the first approach, Hodgkin-Huxley-type models (Hodgkin and Huxley 1952) are arranged to reproduce the intrinsic electrophysiological properties of a generic neuron belonging to a

Reduced Morphology Models, Fig. 2 Schematic representation of different types of neuronal trees and their equivalent cable representation (see Ohme and Schierwagen 1998 for details)

given population as observed from the soma, neglecting the neuron's dendritic structure. This facilitates a more detailed mathematical investigation of the equations, such as bifurcation and phase-plane analysis (see, for instance, Bianchi et al. 2012), which can give useful information on critical model parameters. Multi-compartmental models are instead based on a set

of ad hoc rules that, inspired by the principles of cable theory, implement a full dendritic tree with a few compartments mapping the electric and synaptic properties into a reduced model. This kind of implementation was introduced in the 1990s by Traub et al. (1991), with an empirical 19-compartment model of hippocampal *CA3* pyramidal neurons, followed by a further

Reduced Morphology Models, Fig. 3 A simple neuronal tree and its equivalent cable (Ohme and Schierwagen 1998)

reduction to a two-compartment model (Fig. 4a) by Pinsky and Rinzel (1994). The same strategy was adopted by Davison et al. (2000) for *olfactory bulb mitral cells* (Fig. 4b), who devised a systems of current balance equations for four specific compartments (soma, tuft, primary and secondary dendrite) that included the HH-like equations for the ionic channels. In this case, a rescaling factor and model parameters were determined using the *downhill simplex algorithm* to fit the simplified models with the full model, using two criteria for evaluating goodness of fit (the so-called *fit-to-shape* and *fit-to-time*). The resulting reduced four-compartment model ran 75 times faster than the full model.

The second approach, based on conserving the electrotonic properties of a specific morphology, was originally proposed by Stratford et al. (1989) (the *cartoon model* consisting of 24 compartments) and Bush and Sejnowski (1993) for a deep cortical pyramidal neuron. The cell's morphology was reduced to eight to nine compartments (see Fig. 5) in such a way to preserve the axial resistance of the original model. In this method, all dendrites belonging to a specific functional region (i.e., preterminal and terminal basal dendrites, distal apical and apical dendrites), with approximately the same origin and (electrotonic) length, are collapsed into a single

equivalent cylinder with radius ρ^{eq} and length L^{eq} determined as

$$\rho^{eq} = \sqrt{\sum_i \rho_i^2}, \quad L^{eq} = \frac{1}{N} \sqrt{\sum_i L_i}, \quad (1)$$

where ρ_i and L_i are the radius and the length of the i th dendrite. Since this results in the surface area of the reduced model being lower than in the full model, it required a fine-tuning procedure to find the specific membrane resistance (R_m^{eq}), the specific membrane capacitance (C_m^{eq}), and active properties to obtain the same input resistance of the full model. The reduced models ran approximately five times faster in simulations that included a full set of voltage- and ligand-gated conductances.

A modification of this method to generate simplified representations of thalamocortical (TC) relay cells was proposed in Destexhe et al. (1998). It consisted of merging dendritic branches into equivalent cylinders with radius as in Eq. 1 but length weighted by their respective diameters (ρ_i):

$$L^{eq} = \frac{\sum_i L_i \rho_i}{\sum_i \rho_i}. \quad (2)$$

More recent studies (Destexhe 2001; Tobin et al. 2006) have employed reduction methods

Reduced Morphology Models, Fig. 4 (a) Two-compartment model (Pinsky and Rinzel 1994); (b) four-compartment model showing ion channels and points of stimulation (Davison et al. 2000)

Reduced Morphology Models, Fig. 5 (a) HRP-filled layer 5 (left) and layer 2 (right) pyramidal cells; (b) their reduced models (Bush and Sejnowski 1993)

preserving the total surface area and somatic input resistance of the full model while ignoring its specific axial resistance. In Destexhe (2001), to

reduce the complexity of detailed models, the author identify different functional regions in the dendritic morphology based on the distribution of

Reduced Morphology Models, Fig. 6 (a) Layer VI pyramidal cell from cat parietal cortex; (b) simplified three-compartment model (Destexhe 2001)

synapses in the cell (Fig. 6). The axial resistances of the reduced model are adjusted by a fitting procedure, matching the passive responses and voltage attenuation of the simplified and detailed models.

The reduced model has thus the same membrane area, input resistance, time constant, and voltage attenuation as the detailed model. Similarly, in Tobin et al. (2006) a *leech heart interneuron* was divided into functional regions corresponding to distinct anatomical and physiological roles (Fig. 7). The reduction method included active properties and preserved the surface area of each functional region. However, to improve the correspondence between the reduced and full active models, the axial resistance of several compartments had to be adjusted by fitting procedures.

In Brown et al. (2011) a *preserved path* reduction method was proposed, in which an explicit unreduced path between the soma and a single spine was retained, while reducing the rest of a Purkinje cell morphology (Fig. 8). In this way, the reduction method allows to preserve the essential features of activity in both the soma and a remote dendritic spine. In particular, the length and the radius for each equivalent cylinder are determined taking into account the branching geometries of the cells, i.e.,

$$L^{eq} = L_\alpha - L_\omega, \rho^{eq} = \sqrt{\sum_{seqbr} \rho_{seq} \rho_{br}}, \quad (3)$$

where L_α and L_ω are the anatomic distances to the soma of the closest and farthest dendrites in the cluster, and the quantities ρ_{seq} and ρ_{br} are chosen as the average radius of all the dendrites in the cluster if the dendrites are sequential (seq) or as in Eq. 1 if the dendrites are branched, respectively, i.e.,

$$\rho_{seq} = \frac{1}{N} \sum_i \rho_i, \rho_{br} = \sqrt{\sum_i \rho_i^2}. \quad (4)$$

The procedure conserved axial resistivity, and an iterative procedure was needed to adjust passive and active properties with scaling factors representing the ratio between the surface areas of the dendrites in the full model and the corresponding equivalent cylinders in the reduced version.

The major problem with all the above methods is that none of them take explicitly into account synaptic input locations or non-uniform distribution of ionic conductances. Furthermore, it has been shown (Hendrickson et al. 2011) that for branched neurons in the presence of dendritic synaptic inputs, these methods do not provide significant accuracy (Fig. 9d) or

Reduced Morphology Models, Fig. 7 (a) An oscillator leech heart interneuron; (b) reduced model (Tobin et al. 2006)

Reduced Morphology Models, Fig. 8 (a) Purkinje neuron; (b) reduced model. Preserved electronic path is highlighted in red. The rest of the neuron is reduced to equivalent cylinders (green, smooth; blue, spiny; Brown et al. 2011)

reduction in the number of compartments. In this work, reduced models were created by collapsing the dendritic tree of a full morphological model of a *globus pallidus* neuron (GP, Fig. 9a) in such a way to preserve the total surface area (TSA), electrotonic length (L), and the passive and active parameters. The TSA and L for a given group of dendrites were used to calculate the length L^{eq} and radius ρ^{eq} of the corresponding reduced model compartment using the following two equations:

$$TSA = 2 \pi \rho^{eq} L, L^{eq} = \sqrt{\frac{2R_a}{R_m \rho^{eq}}}. \quad (5)$$

where R_a is the specific axial resistance and R_m is the specific membrane resistance. To test different reduction factors, dendritic subtrees were progressively collapsed (*branched models*) up to a single compartment (*unbranched models*) (Fig. 9b, c).

More general reduction methods using the *iterative rational Krylov algorithm* (Kellems et al. 2009) or a *proper orthogonal decomposition*,

Reduced Morphology Models, Fig. 9 (a) GP neuron; (b) “branched”; (c) “unbranched”; (d) spike time preservation during asynchronous (*top*) and synchronous (*bottom*) synaptic inputs (Hendrickson et al. 2011)

and *direct empirical interpolation methods* (Kellems et al. 2010), have been proposed. In these works, the authors applied a reduction technique to generic passive, quasi-active, and active dendritic tree and reproduce the transmembrane potential at the soma without sacrificing the spatial distribution of inputs. In Kellems et al. (2009), the reduction method reproduced only the sub-threshold dynamics by considering the quasi-active version of the full model, whereas in Kellems et al. (2010) the reduction technique preserves the spatial location of synaptic inputs while reproducing the global voltage dynamics, including both subthreshold and spiking behaviors. These two techniques allow for up to ≈ 15 -fold speedup in simulation time (Fig. 10 for the kinetics and nonuniform channel density from Migliore et al. 1999), but they need a sufficiently rich set of *snapshots* of the voltage dynamics to reproduce the full range of neuronal behavior. This in turn appears to require a setup procedure for every morphology and synaptic configuration that need to be reduced.

In conclusion, although all these methods are often sufficient to take qualitatively into account the somatodendritic interactions that govern spiking or bursting, they present several drawbacks:

- (a) Overall poor results in terms of run time reduction that can be achieved in order to maintain a

relatively good somatic trace accuracy (Brown et al. 2011; Bush and Sejnowski 1993)

- (b) The need, in many cases, of optimization techniques and fine-tuning procedures carried out independently on each neuron that must be reduced (Bush and Sejnowski 1993; Destexhe et al. 1998; Destexhe 2001; Tobin et al. 2006.
- (c) A limited field of application, restricted in most cases to passive dendritic trees and/or without taking into account synaptic input location (Destexhe et al. 1998; Destexhe 2001; Tobin et al. 2006; Brown et al. 2011.

Recently, in Marasco et al. (2012), it has been shown how all these problems can be solved by using a fast and accurate reduction method to simplify models of complex neurons with an arbitrary distribution of active properties, synaptic inputs, and dendritic trees. The new empirical method, tested on a set of hippocampal pyramidal CA1 neurons, was able to map any morphologically and biophysically accurate model of these kind of neurons into equivalent models that can run up to >40 times faster, while maintaining the same average I/O properties. In contrast with all previously published reduction techniques, this method is able to include arbitrary distributions of synaptic inputs and active dendritic conductances without any fitting or parameter tuning procedures (Fig. 11).

Reduced Morphology Models, Fig. 11 Schematic representation of a method to reduce the computational complexity of realistic neuron models (Marasco et al. 2012)

The details of the method are illustrated below. For CA1 neurons, a given morphology is first reduced to nine compartments (see Fig. 11), by clustering dendrites belonging to different functional regions (i.e., soma, axon, apical trunk, apical dendrites (oblique, distal), basal dendrites

(proximal, distal)). The length L^{eq} for each equivalent cylinder is chosen as the sum of the dendrites' length if the dendrites are sequential (seq) or as the average length weighted by their respective areas (S_i) if the dendrites are branched (br), i.e.,

$$L^{eq} = \frac{\sum_{seq, br} S_h L_h}{\sum_{seq, br} S_h}, \quad (6)$$

where

$$L_{seq} = \sum_i L_i, L_{br} = \frac{\sum_i S_i L_i}{\sum_i S_i}. \quad (7)$$

The radius ρ^{eq} for each equivalent compartment is chosen taking into account the axial resistance of the ensemble of dendritic segments it represents (cluster), i.e.,

$$\rho^{eq} = \sqrt{\sum_{seq, br} \rho_h^2}, \quad (8)$$

where

$$\begin{aligned} \rho_{seq} &= \sqrt{\sum_{seq, br} \frac{R_a L_{seq}}{\pi r_{a,seq}}}, r_{a,seq} = \sum_i r_{a,i}, \\ \rho_{br} &= \sqrt{\sum_i \rho_i^2}, \end{aligned} \quad (9)$$

where R_a is the specific axial resistance of each dendrite in the cluster and $r_{a,i}$ is the axial resistance of the i th dendrite.

The specific axial resistance in the equivalent compartment R_a^{eq} is defined as

$$R_a^{eq} = \frac{\pi(\rho^{eq})^2 r_a^{eq}}{L^{eq}}, \quad (10)$$

where

$$\begin{aligned} r_a^{eq} &= \frac{\sum_{seq, br} r_{a,h}}{H}, r_{a,br} = \frac{\prod_i r_{a,i}}{\sum_i r_{a,i}}, \\ \rho_{br} &= \sqrt{\sum_i \rho_i^2}, \end{aligned} \quad (11)$$

and H is the total number of the dendrites in the cluster.

Owing to Eqs. 6, 8, and 10, the membrane area and the axial resistance of the neuron are not conserved in the reduced model; then, a scaling factor ($fact_s^{eq}$) is defined as follows:

$$fact_s^{eq} = \begin{cases} \frac{1}{S^{eq}} \sum_i W_i S_i, & \text{if there are no synaptic inputs,} \\ \frac{1}{S^{eq}} \sum_i S_i, & \text{otherwise,} \end{cases} \quad (12)$$

where S^{eq} is the surface area of the equivalent compartment and $w_i = 1$ if in the i th dendrite there is at least one synapse and 0 otherwise. This factor is used to scale the specific membrane capacitance (C_m), the specific membrane resistance (R_m), and ion channel peak conductance ($\dot{g}_{ionic}$) (see Eqs. 17 and 18). Note that in this way the method takes into account synaptic input location without any fitting or tuning procedures.

To take into account the effect of the i th synaptic input on cluster C of the full model, the *axial path resistance* $r_{i,PATH}$ was used to reposition the input as follows:

$$r_{i,PATH} = \sum_{h=1}^j r_{a,h}, \quad (13)$$

where $r_{a,h}$ is the axial resistance of the h th segment of the *path* consisting of the unique sequence of j segments leading from the soma to the dendrite on which the i th synapse is positioned.

Let $r_{\max}$ and $r_{\min}$ be the maximum and the minimum axial path resistance of cluster C and suppose that this cluster is modeled with a single compartment C', consisting on n' segments (see Eq. 6 in Marasco et al. 2012), in the reduced model. Then, the segment s_i of C' where to place the i th synapse is defined by its axial path resistance $r_{i,PATH}^{eq}$ in such a way that

$$r_{i,PATH}^{eq} \in \left[r_{\min}^{eq} + \sum_{h=1}^{S_i-1} r_{a,h}^{eq}, r_{\min}^{eq} + \sum_{h=1}^{S_i} r_{a,h}^{eq} \right], \quad (14)$$

where

$$r_{\min}^{eq} = \sum_{h=1}^k r_{a,h}^{eq}, r_{\max}^{eq} = \sum_{h=1}^{k+n'} r_{a,h}^{eq} \quad (15)$$

Reduced Morphology Models, Fig. 12 (Top, left) average accuracy obtained for all cells; (top, right) average run time reduction; (bottom) average accuracy for each cell (Marasco et al. 2012)

and k represents the number of segments from the soma to compartment C' and $r_{a,h}^{eq}$ is the axial resistance of the h th segment of C' .

Finally, the passive parameters, the peak conductances of ion channels, and the synaptic inputs are scaled as

$$C_m^{eq} = fact_s^{eq} C_m, R_m^{eq} = \frac{R_m}{fact_s^{eq}}, \quad (17)$$

$$\begin{aligned} \bar{g}_{ionic}^{eq} &= fact_s^{eq} \bar{g}_{ionic}, \\ g_{i,max}^{eq} &= fact_{g_{max}} \frac{r_{i,PATH}^{eq}}{r_{i,PATH}} g_{i,max}, \end{aligned} \quad (18)$$

where $g_{i,max}$ is the original peak conductance of the i th synapse of the full neuron and $fact_{g_{max}}$ is a factor which depends on specific electrophysiological properties of CA1 neurons.

The results (Marasco et al. 2012) showed the accurate mapping of the somatic dynamics of the full models, with a 13–50-fold reduction of the run times (Fig. 12).

An improved version of this method, clustering the compartments according to their Strahler's number, was extended also to Purkinje cells (Marasco et al. 2013). This allows the complete generalization of the method to any type of neuron implemented with any kind of conductance-based model, with arbitrary dendritic distribution of ion channels and synaptic inputs and no need to explicitly take into account special electrophysiological neuron properties. Using this method for Purkinje cells, we demonstrate how run times can be reduced up to 200-fold, while accurately taking into account the effects of arbitrarily located and activated synaptic inputs.

Definition

Reinforcement learning represents a basic paradigm of learning in artificial intelligence and biology. The paradigm considers an agent (robot, human, animal) that acts in a typically stochastic environment and receives rewards when reaching certain states. The agent's goal is to maximize the expected reward by choosing the optimal action at any given state. In a cortical implementation, the states are defined by sensory stimuli that feed into a neuronal network, and after the network activity is settled, an action is read out. Learning consists in adapting the synaptic connection strengths into and within the neuronal network based on a (typically binary) feedback about the

appropriateness of the chosen action. Policy gradient and temporal difference learning are two methods for deriving synaptic plasticity rules that maximize the expected reward in response to the stimuli.

Detailed Description

Different methods are considered for adapting the synaptic weights w in order to maximize the expected reward $\langle R \rangle$. In general, the weight adaptation has the form

$$\Delta w = R \cdot p \text{ PI} \quad (1)$$

where $R = \pm 1$ encodes the reward received upon the chosen action, and PI represents the plasticity induction the synapse was calculating based on the pre- and postsynaptic activity. To prevent a systematic drift of the synaptic weights that is not caused by the covariation of reward and plasticity induction, either the average reward or the average plasticity induction must vanish, $\langle R \rangle = 0$ or $\langle \text{PI} \rangle = 0$.

Reinforcement learning can be divided in these two, not mutually exclusive, classes of assuming that (A) $\langle \text{PI} \rangle = 0$ or (B) $\langle R \rangle = 0$. The first class encompasses *policy gradient* methods while the other, wider class, encompasses *temporal difference* (TD) methods. Policy gradient methods assume less structure as they postulate the required property ($\langle \text{PI} \rangle = 0$) on the same synapse of the action selection module that is adapted by the plasticity. TD methods also involve the adaptation of an internal critique since they have to assure that the required property on the modulation signal ($\langle R \rangle = 0$) eventually holds after learning.

(A) Policy Gradient Methods In the simplest biologically plausible form, actions are represented by the activity of a population of neurons. Each neuron in the population is synaptically driven by feedforward input encoding the current stimulus (Fig. 1). The synaptic strengths are adapted according to the gradient of the expected reward across possible actions. Various learning rules emerge from the different methods of estimating this gradient.

Reinforcement Learning in Cortical Networks, Fig. 1 Population reinforcement learning adapts the synaptic strengths w to the population neurons based on 4 ingredients: the presynaptic activity x , the postsynaptic activity y , the action A encoded in the population activity, and the reward signal R received in response to the action; see Urbanczik and Senn (2009)

In formal terms, sensory stimuli define an input x , e.g., a spike train, that is fed to the network characterized by the synaptic strengths w . This network generates an output y , say again a spike trains, that depends on the synaptic weights w and the input x . Based on y , an action A is selected (Fig. 1). The action is eventually rewarded by a typically binary signal $R(x, A) = \pm 1$ that is fed back to the network where it modulates synaptic plasticity by a global factor. The stimulus presentation, the network activity, and the action selection may have stochastic components. The probability function $P_w(A|x)$ that specifies how likely action A is selected upon input x is referred to as action policy. A policy gradient method considers the expected reward

$$\langle R \rangle = \sum_{x,A} P(x) P_w(A|x) R(x,A) \quad (2)$$

and adapts the synaptic connection strengths w along the reward gradient, i.e., such that the expected weight change satisfies $\langle \Delta w \rangle = \eta \frac{d\langle R \rangle}{dw}$ with some small but positive learning rate η (Williams 1992).

Hedonistic Synapse In the current form, the change in synaptic strength depends on how w affects the likelihood $P_w(A|x)$. But this information may not be available at the single synapse. According to the hedonistic synapse model (Seung 2003), a synapse is only assumed to have access to the very local information of whether there was a release or not ($r_t = 1$ or 0) at time t in response to a presynaptic spike, and x_t itself encodes the presence or absence of a presynaptic spike. We can then write $P_w(A|x) = \sum_r P(A|r) P_w(r|x)$, where $P_w(r|x)$ is parameterized by the variable w and the sum is taken across release trains r . Plugging this into (2) and taking the derivative we obtain

$$\begin{aligned} \frac{d\langle R \rangle}{dw} &= \sum_{r,x,A} P_w(x,r,A) R(x,A) \\ &\quad \times \frac{d}{dw} \log P_w(r|x). \end{aligned} \quad (3)$$

Sampling this gradient leads to updates of w after taking action A in response to the presynaptic spike train,

$$\Delta w = \eta R \frac{d}{dw} \log P_w(r|x). \quad (4)$$

Note that in any case $\langle \frac{d}{dw} \log P_w(r|x) \rangle_r = \sum_r \frac{d}{dw} P_w(r|x) = 0$ because $\sum_r P_w(r|x) = 1$ and hence $\langle \text{PI} \rangle = 0$ as described after Eq. 1.

To obtain an online rule from (4) one low-pass filters $\frac{d}{dw} \log P_w(r_t|x_t)$ to get an eligibility trace that is then multiplied by R to calculate the synaptic update (Seung 2003). If for simplicity we consider a single time interval for a presynaptic spike to occur and an action to be taken, the rule (5) becomes

$$\Delta w = \eta R(r - p)x, \quad (5)$$

where $p = P_w(r = 1 | x = 1)$ is the probability of release that is parametrized by a sigmoidal function of w , $p = 1/(1 + e^{-w})$. In the general case, the plasticity induction $PI = (r - p)x$ is low-pass filtered with a time constant that reflects the delay of the reward (see *Online learning* below).

Spike Reinforcement Since there is only little correlation between specific synaptic releases and rewards given for actions, a more efficient way to estimate the gradient $\frac{d(R)}{dw}$ is to consider the dependence of A on y , as expressed by $P_w(A|x) = \sum_y P(A|y)P_w(y|x)$. Plugging this again into (2) and taking the derivative, we get for the sampled version

$$\Delta w = \eta R \frac{d}{dw} \log P_w(y|x). \quad (6)$$

To illustrate learning rule (6), we can again interpret x and y ($= 1$ or 0) to encode the presence or absence of a spike in a given interval, with the probability p for $y = 1$ being again a sigmoidal function of $u = \sum_i w_i x_i$. Analogously to (5) we obtain the rule $\Delta w = \eta R (y - p)x$ (Williams 1992). Alternatively, x and y may encode firing rates with $y = \phi(u) + \xi$, where $\phi(u)$ is a nonnegative increasing function and ξ some Gaussian noise. We then calculate $\frac{d}{dw} \log P_w(y|x) \propto (y - \phi(u))\phi'(u)x$, and the learning rule becomes

$$\Delta w = \eta R (y - \phi(u))\phi'(u)x. \quad (7)$$

This synaptic plasticity rule depends on 3 factors, (i) the reward, (ii) the postsynaptic quantities (here considered as a single factor), and (iii) the presynaptic activity. For spiking neurons, the corresponding learning rule has been introduced by Xie and Seung (2004) and has been further studied by Pfister et al. (2006); Florian (2007); Frémaux et al. (2010).

Node Perturbation In the framework of spiking neurons, the exploration of the neuronal state space is driven by the intrinsic noise present in the individual neuron's spiking mechanism. A more efficient exploration can be achieved if the noise enters from an external source and can therefore be explicitly tuned. This idea leads to RL based on node perturbation (Fiete and Seung 2006). In the simple coding scenario considered above, node perturbation is formally equivalent to (7), and, with $\xi = y - \phi$, it can be rewritten as

$$\Delta w = \eta R \xi \phi' x. \quad (8)$$

Yet, node perturbation can also be generalized to conductance-based neurons driven by regular “student” input and “exploration” input, and, as before, the plasticity induction $PI = \xi \phi' x$ can again be replaced by a low-pass filtering to comply with delayed reward (Fiete and Seung 2006).

Population Reinforcement When assuming that a synapse has access to the downstream information involved in choosing action A , e.g., via global neuromodulators, the gradient can be well estimated by directly calculating the derivative of (2) with respect to w . The sampling version of this rule is then

$$\Delta w = \eta R \frac{d}{dw} \log P_w(A|x). \quad (9)$$

The action can itself be binary and, e.g., depend on whether the majority of the population neurons did or did not spike in response to the stimulus (Friedrich et al. 2011) or it can be continuous and, e.g., depend on the average population firing rate (Friedrich et al. 2014).

To give an example, we consider a population of N neurons with outputs $y_i = \phi(u_i) + \xi_i$ for $i = 1 \dots N$ that are obtained by an increasing function $\phi(u_i)$ of the weighted input, $u_i = \sum_j w_{ij} x_j$, plus some independent Gaussian noise ξ_i of mean 0. For simplicity we assume ϕ to increase from -1 to $+1$ with $\phi(0) = 0$ and consider binary actions $A = 1$ or $A = -1$ that are taken

stochastically based on the population activity $\mathcal{A} = \frac{1}{\sqrt{N}} \sum_i y_i$ with $P(A = 1 | \mathcal{A}) = (1 + \tanh \mathcal{A})/2$ being a sigmoidal function of $\mathcal{A}$. Neglecting again the indices, the learning rule (9) can then be evaluated to (see Friedrich et al. (2014), Eq. 21 therein)

$$\Delta w = \eta R(A - \tanh \mathcal{A}) \phi'(u) x. \quad (10)$$

Note the formal similarity to (5) and (7) where in the latter the “exploration term” ($y - \phi(u)$) is now replaced by $(A - \tanh \mathcal{A})$. The population reinforcement learning rule (10), however, is composed of 4 factors that originate from 4 different consecutive biological processing stages: (i) the presynaptic activity, (ii) a postsynaptic quantity, (iii) the population activity with the corresponding action, and (iv) the reward. Explicit expressions for (7) and (10) in the case of spiking neurons are given in *spike-timing-dependent plasticity, learning rules*.

Online Learning To obtain online learning rules, one considers an ongoing stimulus x_t that may, e.g., define spike trains up to a discrete time step t . Actions A_t can be taken each moment t , and a reward signal R_t is potentially always present, although it is typically sparse. To express the weight change at each time step t , one considers the so-called synaptic eligibility trace e_t . In the case of the rule (9), this is defined as a low-pass filtering of the instantaneous plasticity induction $\text{PI}_t = \frac{d}{dw} \log P_w(A_t | x_t)$, i.e., $e_{t+1} = \gamma e_t + \text{PI}_t$, with some discount factor $\gamma \in [0, 1)$. Here, the derivative of the log likelihood is evaluated as in (10), with the individual factors each being low-pass filtered to obtain a fully online rule. The final rule then becomes

$$\Delta w_t = \eta R_t e_t. \quad (11)$$

By low-pass filtering the corresponding instantaneous plasticity induction terms PI_t occurring in (5), (7), and (8) (compare with the general form of

Δw given in Eq. 1), one analogously obtains the online version for these rules.

Assuming that the states x_t are sampled from a partially observable Markov decision process (POMDP), the online learning rule (11) can be shown to maximize the expected discounted future reward

$$V_t = \sum_{k=0}^{\infty} \gamma^k \langle R_{t+k} \rangle \quad (12)$$

for each time step t , see Baxter and Bartlett (2001), Theorem 5, for the general case, and Friedrich et al. (2011), Supporting Information, for population learning.

Phenomenological R-STDP Models The gradient-based learning rules discussed so far prevent a systematic weight drift by assuring that the plasticity induction in average vanishes, $\langle \text{PI} \rangle = 0$. This was also assumed in reward-modulated spike-timing dependent plasticity (R-STDP, Izhikevich (2007)). Nevertheless, when considering specific (*in vitro*) data on plasticity induction, one will typically have $\langle \text{PI} \rangle \neq 0$ in Eq. 1 (Sjöström and Gerstner 2010). It is therefore plausible that the reward signal itself in average vanishes. One strategy to achieve this is to subtract the mean reward from the modulating factor such that the learning rule, now reading as $\Delta w = (R - \langle R \rangle) \cdot \text{PI}$, is again unbiased. This leads to the concept of actor-critic learning where a stimulus-specific internal critique adapts the global modulation signal of the plasticity induction to prevent drifts even for individual stimuli. When the LTD part in the STDP window is suppressed and the remaining R-STDP bias is corrected, the learning speed for standard association tasks comes close to the one for gradient-based spike reinforcement (Frémaux et al. 2010).

An elegant solution to solve the reward-bias problem is to assume that the internal reward signal is shaped by a temporal kernel that sums up to zero across time, $\int R_t dt = 0$, and hence a positive internal reward signal must be followed or preceded by a negative one (Legenstein et al.

2008). What appears as a computational trick is reminiscent to the observed relieve from pain in fruit flies (Tanimoto et al. 2004) or the reward baseline adaptation in rodents (Schultz et al. 1997). Along similar lines, pairing reward with differential Hebbian plasticity was also shown to be bias-free and asymptotically equivalent to temporal difference learning (Kolodziejcki et al. 2009).

(B) Temporal Difference (TD) Learning TD methods represent a class of learning rules where the modulatory feedback signal on the level of the synapse is again unbiased. These methods consider a learning scenario where an agent navigates through different states to eventually reach a final rewarding state.

The actor-critic version of TD learning is to calculate a value for each state and to use the value updates to also train the action selection network (Fig. 2). The value of a state x is defined as the expected discounted future rewards when being in that state at time t (Sutton and Barto 1998),

$$V^\pi(x_t) = \sum_{k=0}^{\infty} \gamma^k \langle R_{t+k} \rangle \quad (13)$$

where γ denotes the discounting factor and the expectation $\langle \cdot \rangle$ is taken over all future actions according to a fixed policy π , see Sutton and Barto (1998). While this definition involves future rewards, an online version would again need to estimate the quantity based on only past experiences. It is therefore interesting to note that (13) can be rewritten in a recursive way as $V^\pi(x_t) = \langle R_t \rangle + \gamma V^\pi(x_{t+1})$.

The value function $V^\pi(x_t)$ is assumed to be represented (and approximated) by the activity $V_w(x_t)$ of a given neuron, where w denotes the strength of synapses converging to that neuron and x_t is the input to the network. The synaptic strengths can be adapted online by gradient descent on the error function $E = \langle V(x) - V_w(x) \rangle^2$ with respect to w , where the expectation is over the states x (Sutton and Barto 1998; Frémaux et al. 2013). The weight change at time t is therefore given by

$$\Delta w_t = \eta (V^\pi(x_t) - V_w(x_t)) \frac{dV_w(x_t)}{dw}. \quad (14)$$

Since the true value $V(x_t)$ is not known to the network, it can be approximated as $V^\pi(x_t) \approx R(t) +$

Reinforcement Learning in Cortical Networks, Fig. 2 Actor-critic network for navigation. Based on the current position information, the action network chooses action A that moves the agent towards the neighboring position closest to the site of reward delivery (inside the U-shaped obstacle). The critic network calculates the TD

error δ_t based on the values V and the reward signal R_t . The synaptic strengths w_A and w_V of the action selection and the value representation network, respectively, are both adapted by a TD learning rule. Figure adapted from Frémaux et al. (2013)

$\gamma V_w(x_{t+1})$ by using the recursive definition of $V^\pi(x_t)$. This leads to the learning rule

$$\Delta w_t = \eta \delta_t \frac{dV_w(x_t)}{dw}, \quad (15)$$

where δ_t is called the temporal difference (TD) error and is given by

$$\delta_t = R_t + \gamma V_w(x_{t+1}) - V_w(x_t). \quad (16)$$

If the network that encodes the value $V_w(x)$ consists of a single neuron, say $V_w(x) = \phi(u)$ with $u = wx$, then the synaptic learning rule can be expressed as

$$\Delta w_t = \eta \delta_t \phi'(u) x_t. \quad (17)$$

As compared to the policy gradient rules above, the TD learning rule (17) is obtained by replacing the reward R in Eq. 1 with the TD- δ . Since this δ converges to zero during learning, any systematic weight drift is also suppressed.

As with all reinforcement learning, exploration of the state space is needed to find states associated with more reward or higher values. In policy gradient methods the exploration is enforced by some noise on the synapse, the neuron or the population level (or even at the level of the stimulus selection, see Vladimirov et al. 2009). In TD methods, exploration enters by a noisy action selection and hence, as compared to rules (7) or (8), the noise is implicitly present in the δ .

TD learning in the form of actor-critic has been implemented in spiking neuronal networks (Di Castro et al. 2009; Potjans et al. 2009; Potjans et al. 2011; Frémaux et al. 2013). In these implementations, separate networks for the value representation and the action selection are considered, and the synaptic strengths w in both networks are adapted based on the temporal difference δ_t (Fig. 2). An alternative to this actor-critic learning is to learn values for state-action pairs (“Q-values”) and choose actions based on these values, for instance using the softmax

policy “SARSA”; see Sutton and Barto (1998)). Because the evaluation of a value for a state-action pair in a standard neuronal implementation requires to actually choose that action, however, value evaluation in order to decide for a single next action cannot be implemented in this straightforward form.

Policy Gradient versus TD Methods Both, online policy gradient and TD learning, maximize the discounted future reward as expressed by (12) and (13). But while policy gradient methods do not require specific structures on the network or the task, TD methods do so. First, TD learning assumes an internal representation of states x . Second, the definition of the TD error involves two subsequent states, and hence, value learning requires to sample all the corresponding transitions. Third, to assign values to a state, it is implicitly assumed that the history of reaching that state does not influence future rewards. In fact, TD learning assumes that the underlying decision process is Markovian.

Gradient-based learning does not assume an internal representation of states to which values would be assigned. Neither does gradient-based learning assume Markovianity of the underlying decision process for convergence. When this decision process is not Markovian, TD learning can fail in both ways, by either choosing inappropriate actions while correctly estimating values or by incorrectly estimating the values themselves (Friedrich et al. 2011). Yet, when the decision process is Markovian, TD learning becomes faster than policy gradient learning (Frémaux et al. 2013). Note that a decision process can always be made Markovian by expanding the state-space representation and including hidden states to which again values need to be assigned. To model how the brain can create such hidden states, however, remains a challenge (Dayan and Niv 2008).

Cortical Implementations Due to their conceptual simplicity, policy gradient methods may be implemented in any cortical network that is engaged in stimulus-response associations and that receives feedback via some global

neuromodulator. TD learning was related to basal ganglia where specific networks were suggested to represent values (Daw et al. 2006; Wunderlich et al. 2012), and dopamine activity was suggested to represent the TD error δ_t (Schultz et al. 1997).

Both policy gradient and TD learning are considered as model-free, although TD learning makes use of some information about the underlying model. If more information is included such as state-transition probabilities, the learning can again become faster as less sampling is required to explore the reward function. TD learning methods and their extensions have in particular been proven successful in interpreting human cortical activity during decision-making tasks (for a review, see *Reward-Based Learning, Model-Based, and Model-Free*).

Synonyms

Cytoplasmic resistivity; Intracellular resistivity; R_i (Units: Ω Cm); Specific intracellular (or cytoplasmic) resistance

Definition

The axial resistivity, R_i , is a measure of the Ohmic resistance of the intracellular medium of a neuronal process (e.g., axon or dendrite). R_i is defined as the resistance of the medium contained within a fixed-radius cylinder of unit length and unit cross-sectional area, measured between the flat ends of the cylinder. The most commonly used units are Ω cm, in which case the dimensions of the cylinder are in cm. For neurons, R_i is typically on the order of 100 Ω cm.

Detailed Description

Explanation of the Units

R_i is a specific property of the intracellular medium that should not depend on the dimensions of the cylinder across which it is measured. If the length of the unit cylinder is increased to length L cm, then the total resistance, R_T , measured from one end of the cylinder to the other increases to $R_i L$, because current needs to flow through a greater length of resistive medium. On the other hand, if the radius of the cylinder is increased to a cm, the cross-sectional area of the cylinder becomes πa^2 and R_T decreases to $R_i / \pi a^2$. Intuitively, this is because a larger cross-sectional area provides more parallel pathways for current to flow through the resistive medium, reducing the total resistance. Hence, combining changes to both dimensions of the cylinder, the total resistance R_T (Ω) is given by

$$R_T = R_i L / \pi a^2$$

Because L and a have units of cm, in order to get the correct units of Ω for R_T , the axial resistivity R_i must have the units Ω cm.

Determinants of R_i

It is generally thought that R_i is determined by the presence of mobile ions, mainly monovalent cations (dominated by K^+), that can move freely through the aqueous gel that forms the cytoplasm (Jack et al. 1983). Free diffusion of intracellular ions ensures that R_i is purely Ohmic, as has been confirmed in classic experiments in axons (Hodgkin and Rushton 1946; Hodgkin and Keynes 1953). For technical reasons, R_i is difficult to measure accurately in neurons, leading to variable estimates, particularly in dendrites (Major et al. 1994; Stuart and Spruston 1998; Roth and Häusser 2001). Neuronal modeling typically uses values of R_i in the range 50–400 Ω cm. Recent work has hinted that R_i may be nonuniform and activity-dependent, perhaps because of the plugging of the lumen by the accumulation of

intracellular organelles (Bloodgood and Sabatini 2005; Bekkers 2011).

Applications of R_i

R_i is one of the three fundamental electrical parameters that occur in linear cable theory, the other two being R_m (specific membrane resistance; units $\Omega \text{ cm}^2$) and C_m (specific membrane capacitance; units $\mu\text{F}/\text{cm}^2$). In computational neuroscience, it is usually assumed that intracellular current flow is purely axial, that is, there is negligible radial current. This is achieved if the radius (a) of the cylinder is small compared to its length and if $R_m \gg R_i$. Both of these conditions are generally satisfied in neurons. R_i , together with R_m , appears in an important parameter in linear cable theory, the space constant (or length constant) λ , given by $\lambda = \sqrt{aR_m/2R_i}$. The space constant is a measure of how far current can flow axially without leaking out across the membrane. Intuitively, λ is inversely related to R_i because a lower R_i means it is easier for current to flow axially than to leak out.

Definition

The electrical properties of neural tissue describe how an applied electric field (e.g., biopotentials or electrical stimulation) propagates through the tissue. The complex nature of neural tissue leads to frequency-dependent, inhomogeneous, and anisotropic electrical properties within the tissue.

Detailed Description

Introduction

Electrical properties of neural tissue can be described in terms of electrical impedance. Electrical impedance describes the opposition to the flow

Resistivity/Conductivity of Extracellular Medium, Fig. 1 *Frequency-dependent impedance of biological tissue.* (a) The impedance of biological tissues typically display resistive and capacitive properties. The circuit model in (a) represents a simplified model that has been used to characterize the impedance of biological tissue. R_{DC} represents the resistance that would be measured with direct currents, while R_{∞} represents the resistance that would be measured at extremely high frequencies (frequency $\rightarrow \infty$). (b) The resistive and capacitive properties of biological tissue produce a frequency-dependent tissue impedance. (b) Shows a standard impedance

spectrum that can be measured in biological tissue with each point representing the impedance measured at a specific frequency. The abscissa represents the real part of the impedance (i.e., resistance) while the ordinate represents the negative imaginary part of the impedance (i.e., reactance/capacitance). Tissue impedance spectrum can typically be fit to a semicircle. The example in (b) represents a spectrum with the center of the semicircle along the abscissa; however, the complex frequency-dependent properties of tissue typically cause the center of this semicircle to be shifted below the abscissa. (see McAdams and Jossinet 1995; Foster and Schwan 1996)

of an electrical current through the tissue. Electrical impedance can be a complex quantity with both real (i.e., resistive) and imaginary (i.e., reactive) components. While several studies only consider the resistive component of neural tissue, neural tissue often displays frequency-dependent electrical properties in which it is often useful to consider both the resistive and the reactive components (Fig. 1). The electrical properties and corresponding paths ions travel through the neural tissue are determined by the composition and structure of the tissue. Adequate knowledge of these electrical properties is required to understand the origin of recorded biopotentials and the effects of electrical stimulation on neural tissue.

Frequency-Dependent Behavior

Characterization of the electrical properties of biological tissues has been an intense area of study for well over a century. The main investigative tool has been electrical impedance measurements of tissue samples performed at a wide range of frequencies (Fig. 1). These impedance measurements have shown a clear reactive (i.e., capacitive)

component of biological tissue as well as frequency-dependent changes in both the resistive and reactive components of the tissue impedance. Experiments suggest that at low frequencies, ionic currents largely flow around cells through the extracellular space due to the capacitive nature of cell membranes. At high frequencies, the ionic currents can travel through cell membranes. This process, first described by Höber, is known as the beta dispersion and is largely attributed to the charging of cellular membranes (McAdams and Jossinet 1995; Foster and Schwan 1996). The term, dispersion, describes this dependence of the tissue's permittivity (i.e., capacitance) on the frequency of the applied electric field. Experimental measurements have clearly demonstrated the existence of several dispersions, such as α , β , and γ , at low radio and microwave frequencies, respectively. Detailed descriptions of the dispersions observed in biological tissues are available (see Foster and Schwan 1996). Several publications containing compilations of experimental impedance data for numerous tissue types over a wide range of frequencies are also available (Ranck 1963; Ranck and BeMent 1965; Geddes and Baker 1967; Gabriel et al. 1996a, b).

Volume Conduction of Biopotentials

The frequency-dependent electrical properties of biological tissues have potential implications for both neural stimulation and recording applications. Nervous tissue is a complex environment consisting of a high density of cells and extracellular matrix materials bathed in an electrolyte-rich solution. This environment produces complex paths in which ions can travel.

One of the main reasons for the frequency-dependent electrical properties of biological tissues is the lipid bilayer structure of cell membranes. The capacitive component of cell membranes arises from charge separation that is possible across this lipid bilayer (Sperelakis 2012). Cell membranes also contain ion channels that allow for a resistive component to their impedance. Thus, the impedance of an individual cell is often represented by a parallel combination of resistance and capacitance (Sperelakis 2012). However, at sufficiently low frequencies, the cell membrane is a poor conductor relative to the surrounding electrolyte, and currents are largely limited to the extracellular space (Foster and Schwan 1996).

Although the frequency-dependent electrical properties of neural tissue have clearly been demonstrated, it is less certain how these frequency dependencies affect the volume conduction of biopotentials. There is a significant amount of theoretical and experimental evidence suggesting that the electrical properties of tissue produce a low-pass filtering effect of biopotentials (i.e., attenuation of high-frequency information) due to the capacitive nature of biological tissue (Bedard and Destexhe 2012). There are several possible biophysical properties that could produce this low-pass filtering: inhomogeneities in the biological media, polarization of passive cell membranes (i.e., glia) surrounding a particular neuron, diffusion of ions, and neuron geometry (Linden et al. 2010; Bedard and Destexhe 2012).

Quasi-Static Approximation

Contradictory evidence also exists suggesting frequency-independent volume conduction of

biopotentials (Plonsey and Heppner 1967; Logothetis et al. 2007; Bosetti et al. 2008; Kajikawa and Schroeder 2011). Frequency-independent signal propagation suggests that the resistivity of the tissue dominates and the tissue can be assumed to behave “quasi-statically” (Plonsey and Heppner 1967). By ignoring capacitive, inductive, and wave propagation effects, the quasi-static approximation leads to a major simplification in Maxwell’s equations for use in the analysis and modeling of biological signals (Plonsey and Heppner 1967). Applications exploiting the quasi-static approximation include theoretical analysis of neural stimulation (e.g., deep brain stimulation, transcranial direct current stimulation), theoretical analysis of neural recordings (e.g., action potential recordings, local field potential recordings), and inverse solution/source localization methods (e.g., current-source density analysis) (Mitzdorf 1985; Moffitt and McIntyre 2005; Miranda et al. 2006; Nunez and Srinivasan 2006; Bosetti et al. 2008; Chaturvedi et al. 2010; Lempka et al. 2011; Buzsaki et al. 2012; Lempka and McIntyre 2013).

Tissue Inhomogeneities/Anisotropies

It is also important to note that the structure of the nervous system can produce significant inhomogeneities and anisotropies in its electrical properties. For example, gray and white matter display significant differences in resistivity (Geddes and Baker 1967). The structural organization of white matter produces a high degree of anisotropy (i.e., directionally dependent tissue impedance). Ionic currents traveling parallel to the orientation of the axons experience a lower resistivity relative to the ion currents traveling perpendicular to the axons (Ranck and BeMent 1965). The development of diffusion-weighted magnetic resonance imaging (MRI) has allowed for estimation of the tissue conductivity tensor from the water self-diffusion tensor (Tuch et al. 2001). This discovery has allowed for the development of volume conductor models incorporating detailed tissue inhomogeneities and

Resistivity/Conductivity of Extracellular Medium, Fig. 2 *Tissue anisotropies and inhomogeneities.* The complex structure of neural tissue often results in various anisotropies and inhomogeneities that affect its conductivity profile. It is now possible to use diffusion-weighted MRI to estimate these complexities. The images above illustrate a model of deep brain stimulation (DBS) (yellow volume = thalamus; green volume = subthalamic nucleus) (see Chaturvedi et al. 2010). (a) Individual tensors are displayed as ellipsoids with the color representing the fractional anisotropy (blue = 0; red = 1) and the shape describing both the direction and magnitude of water

diffusion (spherical = isotropic; cylindrical = anisotropic). The red cylindrical tensors show a high degree of anisotropy that is typical of white matter and correspond to the internal capsule. The spherical blue tensors are typical of gray matter. (b) Isolines illustrating the theoretical voltage distribution generated during stimulation from a DBS electrode (blue = low voltage, red = high voltage). This image shows that the complex tissue structure of the brain may lead to an asymmetric voltage distribution during electrical stimulation. (Reproduced from Chaturvedi et al. (2010) with permission from Elsevier)

anisotropies (Fig. 2) (McIntyre et al. 2004; Chaturvedi et al. 2010).

Significance/Implications/Conclusion

The structure and organization of nervous tissue produce complex electrical properties that need to be considered in neural stimulation and recording applications. Inhomogeneous and anisotropic properties can affect the degree and direction of volume conduction. It is also not always clear if potentials propagate through neural tissue in a frequency-dependent or quasi-static manner. Characterization of the electrical properties of biological tissue still remains an active area of research, and only with an adequate knowledge of these properties can we understand the origin of biopotentials and the effects of electrical stimulation on neural tissue.

Retinal Disease and Remodeling

Robert E. Marc

John A. Moran Eye Center, University of Utah, Salt Lake City, UT, USA

Definition

Retinal remodeling is a collection of pathologic changes in the structure and function of the neural retina triggered by photoreceptor degenerations.

Detailed Description

Diseases That Cause Retinal Remodeling

Retinal remodeling is initiated by inherited gene defects and gene-risk coupled environmental stressors that lead to photoreceptor degeneration (Jones et al. 2003, 2012; Marc et al. 2003), e.g.,

retinitis pigmentosa (RP) and macular degeneration (AMD). Over 100 gene loci are associated with RP-like degenerations (Daiger and Sullivan 2013). Most RP-like degenerations directly affect rods, leaving many cones intact. Rod death can, however, trigger extensive bystander killing of cones. These different effects have been classified as *cone sparing* and *cone decimating* (Marc et al. 2007). After photoreceptor death, the surviving retina progressively changes form and signaling properties. Remodeling progression depends on the nature of the primary degeneration. Recessive RP often triggers rapid remodeling. Slower autosomal dominant RP may take a year or two to deplete photoreceptors and trigger remodeling in experimental animals and many years in humans. Decades of advanced RP or AMD generate severely remodeled zones in humans (Jones et al. 2003, 2012).

Remodeling Phases

Remodeling occurs in phases (Marc et al. 2003, 2007). In phase I, stressed photoreceptors retract or extend their synaptic terminals, disrupting connectivity with their target bipolar and horizontal cells. In phase II, photoreceptor cell death and ablation of the outer nuclear layer lead to extensive bipolar cell remodeling. In cone-decimating disease, all bipolar cells retract their dendrites. In cone-sparing disease, rod bipolar cells retract their dendrites from dying rods and attempt to establish sparse connections with survivor cones. After the cones die, phase III remodeling ensures with (1) glial hypertrophy and formation of a dense (non-scar) distal seal: a barrier to transport between the surviving retina and the retinal pigmented epithelium (RPE); (2) de novo neuritogenesis by survivor neurons; (3) evolution of synaptic microneuromas throughout the retina, thus scrambling networks; (4) pathologic migration of neurons to ectopic sites and occasional emigration into the choroidal space; (5) progressive neuronal cell death, with bipolar cells dying more rapidly than amacrine or ganglion cells; (6) retinal invasion and encapsulation of retinal vessels by the RPE; and (7) alterations in glial and neuronal gene expression. Most aspects of phase III are prevented in cone-sparing pathologies. Cone

survival appears key to maintaining the dendritic arbors of cone bipolar cells. However, even in cone-sparing disease, rod bipolar cells display massive dendritic remodeling, retargeting to cones, with concomitant reprogramming of their normal metabotropic ON glutamate receptors to ionotropic OFF glutamate receptors (Marc et al. 2007).

Mechanisms and Physiology of Remodeling

The mechanisms of remodeling are not yet well understood. Similar to rewiring after brain trauma, retinoic acid receptor (RAR) pathways appear necessary for de novo neuritogenesis. All elements of retinoic acid synthesis and signaling pathways are expressed in the degenerating retina, and RAR signaling inhibitors may prevent neuritogenesis (Lin et al. 2011). The mechanisms driving new synapse formation and cell migration are unknown. As the strength of photoreceptor signaling decreases in phase II, network signal-to-noise ratios decrease, with extensive light-independent spiking in retinal ganglion cells (Margolis et al. 2008). This appears partly due to spread of corruptive signals via gap junctions (Toychiev et al. 2013). Spontaneous retinal self-signaling persists well into phase III, after total loss of photoreceptors (Marc et al. 2007).

Consequences

Remodeling corrupts retinal networks, impacting the outcomes of prospective interventions such as induced pluripotent stem cell implants, fetal tissue transplants, and gene, optogenetic, photochemical, or retinal prosthetic chip therapies (Jones et al. 2012; Marc et al. 2005). There is no evidence that remodeling is interrupted by any intervention.

Definition

Vision is a complex, computationally demanding, perceptual task that begins at the retina, a layered sheet of tissue, 200–300 μm thick, that lines the

posterior part of the eye. The cornea and lens of the eye focus light rays onto the retina, leading to the activation of photoreceptors located in the back of the retina. The photoreceptors are one of the five major classes of neurons in the retina, the other four being bipolar cells, horizontal cells, amacrine cells, and ganglion cells, the output neurons of the retina. Within each class of neuron, there are a number of different types based on morphological and/or functional criteria, and current estimates are that in all there are more than 60 different cell types in the mammalian retina (Masland 2012).

Detailed Description

The photoreceptor layer (PRL), shown in Fig. 1, comprises two classes of photoreceptor, rods and cones. Rods are highly sensitive and primarily operate under low light conditions. Cones are less sensitive, but highly adaptive, operating over a vast range of light intensities. The human retina contains three types of cone (but only one type of rod), short (S), middle (M), and long (L) wavelength cones that are maximally sensitive to light of varying wavelengths (420 nm, 530 nm, and 560 nm, respectively) allowing for trichromatic color vision.

Photoreceptors convey their light information to bipolar cells of which there are 10–12 types. This signal transfer occurs in the outer plexiform layer (OPL) where this signal can also be modulated by laterally situated horizontal cells. Two main functional classes of bipolar cells exist in the mammalian retina: those that depolarize in response to a “light on” signal from photoreceptors, ON bipolars, and those that hyperpolarize, OFF bipolars. This organization is thought to function to make small changes in irradiance more conspicuous and to segment contrast polarity (increasing or decreasing irradiance) for the purposes of perception (Westheimer 2007). Bipolar cells (and photoreceptors) generally encode light information by graded changes in membrane potential rather than produce action potentials (Morgans 2000). This means light intensities can be reported, at this early stage of light signaling, continuously in an analogue fashion, before the

Retinal Neurophysiology, Fig. 1 Light pathways through the retina. Light hyperpolarizes both rod and cone photoreceptors. They transfer this signal via either a sign-conserving (green arrow) or sign-inverting (red arrow) chemical synapse. Cone signals pass to depolarizing ON or hyperpolarizing OFF bipolar cells and then to ON and OFF ganglion cells, respectively.

Rod signals are passed to depolarizing ON rod bipolar cells to All amacrine cells where they subsequently enter the cone circuitry via gap junctions (red tube) to cone ON bipolars or to cone OFF bipolars via inhibitory synapses. Alternatively, rod signals can be passed directly to cones via rod/cone gap junctions where they enter the cone circuitry at an earlier stage

signal is processed by the retinal circuitry and digitally encoded into a train of action potentials in the retinal ganglion cells (RGCs).

Cone photoreceptors form synapses with both ON and OFF bipolar cells, whereas rods primarily form synapses only with ON rod bipolars (Wässle and Boycott 1991). Figure 1 summarizes the flow of light information from rods and cones to RGCs. Both ON and OFF cone bipolar cells synapse directly onto RGCs in different layers of the inner plexiform layer (IPL) where they contact respective ON and OFF (or small bistratifying ON/OFF) retinal ganglion cells (RGCs). OFF bipolar cell to OFF RGC connections occur in the “OFF” lamina closest to the INL, and ON connections occur in the “ON” lamina, closer to the ganglion cell layer (GCL) (Hartveit 1997). Rod bipolar cells generally do not synapse directly onto ganglion cells; instead, they synapse onto a specific type of amacrine cell, the AII amacrine (Sharpe and Stockman 1999). These cells have been shown to subsequently infiltrate the main cone circuitry by exciting ON cone bipolar cells through electrical gap junctions and

inhibiting OFF cone bipolar cells through glycinergic synapses (Kolb and Famiglietti 1974; Muller et al. 1988). Gap junctions also exist between rods and cones (and between rod/rod and cone/cone), providing another avenue for rod signals to reach RGCs (Sterling and Demb 2004). Other types of amacrine cells are generally situated in the IPL and are orientated horizontally. This allows these cells to greatly influence the transfer of information from bipolar cells to ganglion cells.

The output from the retina is via retinal ganglion cells (RGCs) that form the innermost neural layer of the retina. The axons of RGCs leave the eye as the optic nerve and convey visual information to the brain regions in the form of action potentials. In the primate retina, there are more than 15 morphologically distinct RGCs; however, two types make up the greatest proportion of RGCs: parasol RGCs (alpha cells are the homologue in cat retina) make up about 5% of all ganglion cells, and midget RGCs (beta cells are the homologue in cat retina), about 70–80% of all ganglion cells (Dacey 2004; Wässle 2004). The

receptive field of RGCs shows a concentric organization whereby the central region of the receptive field is enclosed by an antagonistic surround: producing RGCs with an ON center/OFF surround and OFF center and ON surround, depending on their pattern of connectivity with bipolar cells in the IPL. This classical description of the RGC receptive field organization has recently been shown to be much more dynamic than previously thought (see Masland 2012). In addition to the ON/OFF response classification, many midget RGCs also display a chromatic contrast sensitivity, with the receptive field centers and surrounds receiving input from either M or L cones/bipolar cells, underpinning the red/green opponent pathway. The small bistratified RGCs receive chromatic input from S cones and a combined M + L cone input, underpinning the blue/yellow opponent pathway (Martin 1998). The midget RGCs respond best to higher spatial frequencies and lower temporal frequencies and display high chromatic contrast sensitivity. Parasol RGCs on the other hand are most responsive to lower spatial frequencies, to higher temporal frequencies, and to differences in retinal luminance. Midget, parasol, and small bistratified RGCs make up approximately 80% of the RGC population in the primate retina. The function of many of the RGCs that make up the remaining 20% remains largely unknown. One such RGC type that constitutes less than 1% of RGCs in the primate retina (Dacey et al. 2005) is intrinsically light sensitive and has been shown only recently to contain the photopigment melanopsin (Berson 2003). These RGCs are thought to play a significant role in circadian rhythms and the pupillary light reflex, as well as a variety of other non-image-forming functions, and are now thought to contribute to perceptual vision (Lucas 2013).

Retinal Waves, Models of

Matthias H. Hennig
Institute for Adaptive and Neural Computation,
School of Informatics, University of Edinburgh,
Edinburgh, UK

Definition

The developing retina displays spontaneous activity characterized by correlated, propagating activity

patterns (Wong 1999; Blankenship and Feller 2010). Retinal waves are hypothesized to provide cues for the development of retinal receptive fields and projections from the retina to higher visual brain areas (Sernagor et al. 2001; Torborg and Feller 2005). Several computational models have been developed to simulate retinal waves, which have helped to shed light on the mechanisms involved in their generation (Godfrey and Eglen 2009). Two different approaches have been used in these models; they simulate networks either as cellular automata or using biophysical neurons models. These models also provide tools for generating synthetic activity to investigate the role of retinal waves in models of visual system development.

Detailed Description

Since their discovery in 1988 (Galli and Maffei 1988; Wong et al. 1993), there has been intensive research into the mechanisms underlying retinal waves using both experimental and computational approaches. Retinal waves undergo several major developmental changes. Each stage has a different pharmacological profile, indicating that the network activity is supported by different pathways and transmitter systems (Blankenship and Feller 2010). Efforts to model retinal waves have so far exclusively focused on acetylcholine-dependent waves during early developmental stages because these are experimentally the best understood.

Refractoriness as a Central Mechanism

The first key insight came from a model by Feller et al. (1997) and Butts et al. (1999). This work was based on the following four assumptions, which were subsequently each confirmed experimentally:

1. Waves are initiated by cell-autonomous, spontaneous activity in cholinergic amacrine cells.
2. Neural activity propagates laterally in a recurrently connected network of amacrine cells through excitatory synapses (Fig. 1a).
3. Activity drives amacrine cells into a long-lasting refractory state, which restricts the

propagation of subsequent wave into regions of non-refractory neurons (Fig. 1b–d).

4. Retinal ganglion cells read out the wave activity from the starburst amacrine cells and transmit it to higher areas in the visual system (Fig. 1a)

This model, implemented as a cellular automaton with simple threshold units, produces propagating, wavelike activity patterns in the simulated ganglion cell layer replicating several properties of retinal waves. In particular, it was able to reproduce the two hallmark properties of cholinergic waves: subsequent waves are nonoverlapping, and the whole retina is uniformly covered by waves over time. The model could be tuned such that the simulated wave size and frequency distributions closely matched those recorded from the ferret retina with calcium imaging.

Butts and Feller showed that a refractory mechanism is sufficient to control the spatiotemporal propagation of activity in this otherwise purely excitatory recurrent network. Only non-refractory regions on the retina can be invaded by an active wave, so the recent history of activity limits the spreading of activity. This prediction is consistent with later data from patch clamp recordings from starburst amacrine cells showing that a slow after-hyperpolarization (sAHP, Fig. 1b) conductance constitutes a strong, cell-intrinsic refractory mechanism (Zheng et al. 2006).

A problematic assumption in this model was that ganglion cells had to filter the more random amacrine cell activity to produce spatiotemporally compact waves, while paired recordings later demonstrated that amacrine and ganglion cell activities are tightly correlated (Zheng et al. 2006). This indicates that the spatiotemporal properties of cholinergic waves are already present in the amacrine cell network.

Activity-Dependent Refractoriness

The fact that the main properties of retinal waves are already present in the network of cholinergic amacrine cells and are primarily inherited by

Retinal Waves, Models of, Fig. 1 Illustration of simulated cholinergic retinal waves with the model by Hennig et al. (2009). (a), Schematic view of the network architecture generating retinal waves. Neural activity is spontaneously generated in cholinergic amacrine cells and propagates laterally across the network. Retinal ganglion cells receive excitatory input from amacrine cells and read out their activity. (b), Spontaneous events (top) and events triggered by synaptic input during waves (bottom) cause large Ca^{2+} spikes in amacrine cells. These spikes subsequently activate a slow afterhyperpolarization conductance, which puts neurons into a long-lasting refractory state.

Wave events cause a stronger activation, which recovers more slowly than intrinsic, spontaneous spikes. (c), Simulated network activity exhibits a mix of synaptically driven spikes and spontaneous intrinsic events. The former synchronize the network through strong synaptic currents (bottom), while the latter desynchronize the network through refractoriness. (d), A simulated wave event. Propagation of activity is seen in the membrane potential (left) and the synaptic currents (middle). The activity leaves a trail of refractory neurons. Also visible are other refractory regions from preceding activity, which cannot be invaded by the current wave

ganglion cells was addressed in a more recent model by Godfrey and Swindale (2007). It was again implemented as a cellular automaton, and it incorporated new findings on cholinergic amacrine cell physiology (Zheng et al. 2006). While overall very similar to the model by Feller et al. (1997), it was assumed that the duration of the refractory state of amacrine cells depends on the amount of synaptic input received (Fig. 1b). Stronger input then causes stronger activation of the refractory mechanism, and a linear relaxation function ensures that such differences in activation result in pronounced differences in recovery time. As a result, the refractory state of amacrine cells in the center of waves lasts longer than near wave boundaries, introducing a further dependence on the previous history of excitation. This model could reproduce typical wave size and frequency distributions from a range of species, as measured by calcium imaging, without requiring the filtering of amacrine cell activity by the ganglion cells. It also suggested that the network producing retinal waves may have chaotic dynamics.

Between Local and Global Functional Connectedness

To better reproduce data from patch clamp recordings (Zheng et al. 2006), a study by Hennig et al. (2009) provided a biophysically plausible model of retinal waves. Cholinergic amacrine cells were implemented as Morris-Lecar-type models that produce prolonged calcium channel-mediated bursts in response to depolarization (Fig. 1b–d). Bursts are then triggered either by a cell-intrinsic noise source or by multiple sources of synaptic input from neighboring neurons. Importantly, in this model only the latter events cause sufficient transmitter release and then also trigger bursts in connected neurons.

This model also placed a refractory mechanism, implemented as a calcium-dependent sAHP conductance, at the heart of the regulation of propagating activity (Fig. 1b). Critically, it was assumed that the sAHP was activated on two different time scales, which

reproduced an activity-dependent refractoriness similar to that in the Godfrey and Swindale (2007) model. Simulations showed that this multi-scale refractory mechanism can desynchronize network activity while maintaining spatially correlated activity typical for cholinergic retinal waves.

Thus, the network can be set up to operate either in a highly correlated regime, where most waves spread across the whole retina, or in a strongly decorrelated regime, where activity can only propagate over small distances. The transition point between these two states corresponds to a continuous (second-order) percolation phase transition, where wave sizes and durations assume power law distributions (Ódor 2004). An analysis of multielectrode array recordings of waves from turtle and mouse retina indicated that cholinergic retinal waves indeed show the scale-free properties that characterize the network state near the phase transition.

The idea that retinal waves may result from dynamics close to a percolation phase transition was also formulated by Albert et al. (2008), who showed that such patterns can be used to train receptive fields similar to those found in visual cortex. This behavior resembles neural avalanches observed in a range of preparations (Plenz and Thiagarajan 2007; Beggs and Timme 2012). A common feature of this form of activity is that it contains events on all length scales, which are unbiased with respect to scale or sequence and as such resemble lower-order natural image statistics.

Summary

The existing models of cholinergic retinal waves provide satisfactory explanations for the mechanisms responsible for their generation and propagation. More recent experimental work should make it possible to implement models for other developmental stages, such as early waves mediated by gap junctions and late waves that depend on extrasynaptic glutamate diffusion (Blankenship and Feller 2010). In particular for the latter, the precise mechanisms and network connectivity are still under investigation, and models can help to

uncover these factors. It is also worth noting that the mechanisms investigated in these models are based on fairly generic properties of neurons and therefore potentially also relevant in other areas of the nervous system, which also show spontaneous activity during development (Blankenship and Feller 2010).

Definition

Axons of neighboring retinal ganglion cells (RGCs) coming from the eye normally terminate in neighboring parts of target brain regions, such as the optic tectum of amphibians or the superior colliculus (SC) and lateral geniculate nucleus of

mammals. This orderly arrangement of connections is termed a retinotopic map. Theoretical models of retinotopic map formation help us understand how these connections develop in early life and how maps might reform after surgical or experimental manipulations.

Detailed Description

What Is a Retinotopic Map?

A projection of connections is termed a topographic map when neighboring neurons in the source region project to neighboring regions in the target. Topographic maps are found in many sensory systems. Perhaps the most-studied topographic map is the projection from the retina to primary targets in the brain, which ensures that the overall layout of the visual image is preserved as it is sent to the brain (Fig. 1). Topographic maps in the visual system are often termed retinotopic maps.

In principle a topographic map can emerge through *local* interactions between neighboring neurons (Willshaw and von der Malsburg 1976). However, local mechanisms alone cannot generate the *global* order observed in maps, whereby one region of the retina consistently projects to the

same region of the target in different animals. For example, in mouse, neurons in the temporal retina consistently project to anterior SC (Fig. 1). Hence, retinotopic maps contain both local and global order.

Mechanisms of Map Formation

Here I describe three key mechanisms proposed to drive the formation of retinotopic maps (Cang and Feldheim 2013).

Molecular Gradients

Early experiments into regrowth of retinal axons following surgical manipulations suggested that RGCs tended to regrow to predefined target locations (Sperry 1963). Sperry therefore proposed that neurons in the retina and target had unique molecular labels that encoded this preference (Sperry 1963). The abilities of such molecular labels to establish retinotopic maps were established computationally by von der Malsburg and Willshaw (1977), long before any molecular cues had been discovered. The first molecular cues identified were the Eph receptor and ephrin ligand families (Drescher et al. 1997). These proteins are distributed across the retina in a graded fashion (Fig. 1) such that neighboring neurons in the retina or target express similar

Retinotopic Development, Models of, Fig. 1 The retinotopic map in the mouse ensures that the retinal image is preserved as it projects to the superior colliculus (SC). *Dark red* and *blue* triangles denote the relative expression levels of Ephs and ephrins in the retina

and SC (see “Molecular Gradients”). Lighter triangles indicate counter-gradients. (Figure adapted from Sterratt and Hjorth (2013) with permission from Cambridge University Press)

levels of these proteins, and there is a consistent bias (e.g., EphA receptor is always highest in the temporal retina).

The mouse visual pathway contains two gradient families, the A system and the B system, across the two axes of the retina and target. The A system is repulsive: temporal RGCs have high levels of EphA and terminate in anterior SC, where ephrin-A levels are lowest. Nasal RGCs have low levels of EphA and terminate in posterior SC, where ephrin-A levels are highest. By contrast, the EphB system is attractive, such that the ventral retina (with high levels of EphB) projects to medial SC (with high levels of ephrin-B). Cross talk between A and B systems, counter-gradients (Fig. 1), and other proteins may also contribute to map formation (Cang and Feldheim 2013). Molecular gradients thus provide both local order (neighboring neurons express similar protein levels) and global order (gradient directions are consistent between animals). A recent computational modeling study has evaluated different hypotheses by which these gradients might contribute to map formation (Triplett et al. 2011).

Spontaneous Neuronal Activity

The pioneering model of Willshaw and von der Malsburg (1976) proposed that correlated activity in neighboring RGCs could provide appropriate cues for the development of ordered maps. Experimental evidence for such patterned activity came 14 years later (Maffei and Galli-Resta 1990). Early in postnatal development, before the retina is visually responsive, RGCs generate spontaneous neuronal activity. These activity patterns are often termed “retinal waves” as the activity propagates across the retina (Wong 1999). Correlated RGC activity induces correlated activity in mouse target regions (Siegel et al. 2012; Ackman et al. 2012). Hebbian-based activity-dependent refinement can adapt initially weak synapses between RGCs and SC neurons to ensure that (1) SC neurons receive inputs from coactive neighboring RGCs and (2) neighboring SC neurons receive inputs from neighboring RGCs. Activity-based refinement generates local, but not global, order (Willshaw and von der Malsburg 1976).

Competition for Resources

A third key mechanism is that of competition for limited resources. For example, SC neurons can receive only a finite amount of inputs, and RGC axons can make only a limited amount of contacts. Competition comes in many forms, which can be described by a class of mathematical structures (van Ooyen 2001). The importance of competition in map formation can be tested by altering neuronal numbers in either the retina or target. Reducing retinal cell numbers affects the maps generated in mouse, but does not alter zebrafish RGC projections (Triplett et al. 2011). Competition can also be used instead of counter-gradients to generate maps (Sterratt 2013).

Future Directions

Many computational models have been proposed for the formation of retinotopic maps (Goodhill and Xu 2005; Goodhill 2007) and show how retinotopic order might interact with the development of other map properties, such as ocular dominance or orientation preference (Swindale 1996). Recent experimental advances in mouse genetics and imaging have generated more quantitative descriptions of retinotopic maps that should help us discriminate which mechanisms are important for map formation. Our recent unpublished work suggests that no single model can yet account for all quantitative data on retinotopic map formation in mouse. It is therefore likely that new models are still needed to account for modern experimental results.

Definition

Reinforcement learning (RL) techniques are a set of solutions for optimal long-term action choice

This is an updated version of the entry originally published as Huys Q.J.M., Cruickshank A., Seriès P. (2014) Reward-Based Learning, Model-Based and Model-Free. In: Jaeger D., Jung R. (eds) *Encyclopedia of Computational Neuroscience*. Springer, New York, NY.

such that actions take into account both immediate and delayed consequences. They fall into two broad classes: model-based and model-free approaches. Model-based approaches assume an explicit model of the environment and the agent. The model describes the consequences of actions and the associated returns. From this, optimal policies can be inferred. Psychologically, model-based descriptions apply to goal-directed decisions, in which choices reflect current preferences over outcomes. Model-free approaches forget any explicit knowledge of the dynamics of the environment or the consequences of actions and evaluate how good actions are through trial-and-error learning. Model-free values underlie habitual and Pavlovian conditioned responses that are emitted reflexively when faced with certain stimuli. While model-based techniques have substantial computational demands, model-free techniques require extensive experience.

Detailed Description

Theory

Reinforcement Learning

Formally, reinforcement learning (RL; Sutton and Barto 1998) describes a type of solution to Markov decision process (MDP) problems, which are defined by a tuple $\mathcal{S}, \mathcal{A}, \mathcal{T}, \mathcal{R}, \pi$:

- $\mathcal{S}$: a set of states $s \in \mathcal{S}$.
- $\mathcal{A}$: a set of actions $a \in \mathcal{A}$.
- $\mathcal{T}(s'|s, a)$: the transition function maps each state-action pairs to a distribution over successor states s' , with $s, s' \in \mathcal{S}; a \in \mathcal{A}$ and $\sum_{s'} \mathcal{T}(s'|s, a) = 1$.
- $\mathcal{R}(s, a, s') \rightarrow r$: the reinforcement function mapping state-action-successor state triples to a scalar return r .

The goal is to determine a policy $a \leftarrow \pi(s)$ that maps each state to the action maximizing the total expected future return of actions a in state s .

$$\begin{aligned} a^* &\leftarrow \operatorname{argmax}_a Q(s, a) \text{ where } Q(s, a) \\ &= \mathbb{E} \left[\sum_{t'=0}^{\infty} r_{t'} | s, a \right] \end{aligned} \quad (1)$$

where the sum over the future returns results from the fact that choices lead both to immediate returns but also have longer-term consequences.

The sum in Eq. 1 may not be finite. For this reason, it is often replaced by the discounted total expected reward $\mathbb{E} \left[\sum_{t'=0}^{\infty} \gamma^{t'} r_{t'} | s, a \right]$ with the discount factor $0 \leq \gamma \leq 1$. The discount factor sets the relative importance of immediate and future rewards: $\gamma = 0$ means that only the next reward is considered, whereas $\gamma = 1$ considers all rewards to have equal importance no matter how far in the future they occur.

Model-Based RL

Model-based RL assumes knowledge of the transition matrix $\mathcal{T}$, the reward function $\mathcal{R}$, and the state and action spaces $\mathcal{S}, \mathcal{A}$ which define the model of the world. This means that the expectation in Eq. 1 can be written explicitly in terms of $\mathcal{T}$ and $\mathcal{R}$ as the *Bellman equation* (Bellman 1957):

$$Q(s, a) = \sum_{s'} \mathcal{T}_{ss'}^a [\mathcal{R}(s, a, s') + V(s')] \quad (2)$$

$$\text{with } V(s') = \max_{a'} Q(s', a') \quad (3)$$

The Q value is the long-run expected return for taking action a in state s . The optimal policy maps each state to the action with the highest Q value:

$$\pi^*(s) \leftarrow \operatorname{argmax}_a Q(s, a). \quad (4)$$

Equation 3 represents a recursive definition of a decision tree of width w (determined by the number of actions $|\mathcal{A}|$ and the size of the state-space reached by these actions). The computational cost of simple tree search is $O(w^d)$ where d is the depth of the tree (see Fig. 1 for an example). Although dynamic programming methods such as policy iteration reduce this cost to $O(|\mathcal{S}|^3)$, this is still computationally prohibitive

Reward-Based Learning, Model-Based and Model-Free, Fig. 1 Example decision tree. The problem consists of first choosing between actions a1 and a2, each of which has three possible outcomes, followed by choosing between actions a3 and a4, each of which has another three possible outcomes that might depend on which

action/outcome preceded them. Actions are shown in solid black and outcomes as empty circles. Optimal action choice requires evaluation of all the branches. In this simple problem, with a sequence of two choices, each leading to three possible outcomes, the tree has width $w = 6$, depth $d = 2$, and $w^d = 36$ branches. (Adapted from Huys 2007)

for most real-life problems and additionally difficult to implement neurally as it involves matrix inversion. Psychological and neurobiological accounts of model-based RL thus emphasize sequential evaluations of decision trees.

Model-Free RL

Model-free RL methods apply to situations where agents do not know $\mathcal{T}$ and $\mathcal{R}$ where the decision trees are too complex to evaluate. They approximate the expectations in Eq. 1 by sampling from the world. *Temporal difference reinforcement learning (TDRL)* constructs estimates of state or state-action values from these samples by bootstrapping. To achieve this, the total future reward is written as the sum of the immediate reward plus the average value of the successor state:

$$\begin{aligned} \mathcal{V}^*(s) &= \mathbb{E} \left[\sum_{t=0}^{\infty} r_t | s \right] = \mathbb{E} \left[r_0 + \sum_{t=1}^{\infty} r_t | s \right] \\ &= \mathbb{E} [r_0 + \mathcal{V}^*(s') | s] \\ &= \mathbb{E} [r_0 | s] + \mathbb{E} [\mathcal{V}^*(s') | s] \end{aligned} \quad (5)$$

For approximate values $\mathcal{V}$, Eq. 5 does not hold:

$$\widehat{\mathcal{V}}(s) \neq \mathbb{E} [r_0 | s] + \mathbb{E} [\widehat{\mathcal{V}}(s') | s] \quad (6)$$

Letting the difference between the two sides be δ_t , one can arrive at correct values by iterative updates

$$\widehat{\mathcal{V}}_{i+1}(s) \leftarrow \widehat{\mathcal{V}}_i(s) + \epsilon \delta_V \quad (7)$$

with $0 \leq \epsilon \leq 1$.

TDRL combines such iterative updates with sampling. Instead of evaluating the expectations, it assumes that agents can repeatedly generate actions from their (suboptimal) policy at $a_t \sim \pi(s_t)$ and on the t 'th such interaction obtains state and reward samples from the world:

$$s_{t+1} \sim \mathcal{T}(s | s_t, a_t) \quad (8)$$

$$r_t \sim \mathcal{R}(s_t, a_t, s_{t+1}) \quad (9)$$

These samples are used to approximate the expectations, letting

$$\delta_t = r_t + \widehat{\mathcal{V}}_t(s_{t+1}) - \widehat{\mathcal{V}}_t(s_t) \quad (10)$$

$$\widehat{\mathcal{V}}_{t+1}(s_t) \leftarrow \widehat{\mathcal{V}}_t(s_t) + \epsilon \delta_t \quad (11)$$

A similar approach can be applied to learning state-action values (Watkins and Dayan 1992). Thus, while model-based RL methods

prospectively predict the consequences of actions based on an understanding of the structure of the world, model-free methods retrospectively approximate these based on past experience. Nevertheless, under certain situations, model-free methods have strong convergence guarantees (Bertsekas and Tsitsiklis 1996; Sutton and Barto 1998; Puterman 2005). Policies π are often in turn formalized as parametric functions of the value functions $\mathcal{V}$ or Q themselves, although this may break certain guarantees (Bertsekas and Tsitsiklis 1996).

One biologically important variation of a reinforcement learning algorithm is the **Actor-Critic** (Barto et al. 1983). The Critic uses TD to estimate the value $\mathcal{V}_t(s)$ for states, while the Actor maintains the policy used to select actions. After each action a_t , the Critic calculates the prediction error and sends it to the Actor. A positive prediction error indicates that the action improved the potential for future rewards, and the tendency to select the action should be increased. An example of using the prediction error is to select actions based on the Gibbs softmax method

$$\pi_t(s, a) = \frac{e^{p_t(s, a)}}{\sum_{a'} e^{p_t(s, a')}} \quad (12)$$

where $p_t(s, a)$ defines the “propensity” to take action a in state s . These propensities are updated by the prediction error $p_t(s, a) \leftarrow p_{t-1}(s, a) + \epsilon \delta_t$.

Sampling and Computational Costs

The algorithms discussed so far suffer either from catastrophic computational requirements or from equally drastic dependence on extensive sampling in realistic environments. Solutions to these drawbacks fall into four general categories: (1) subdivision into smaller subtasks (possibly each having their own subgoal; cf. Dietterich 1999; Sutton et al. 1999); (2) pruning of the decision tree (cf. Knuth and Moore 1975; Huys et al. 2012); (3) approximations (e.g., neural networks for function approximation, Sutton and Barto 1998; or (4) structured representations (Boutillier et al. 1995) and sampling techniques (Kearns and Singh 2002; Kocsis and Szepesvari 2006).

A fourth approach, the successor representation (Dayan 1993), involves rewriting Eq. 5 by observing that the total expected future rewards involve repeatedly summing over the same reward but weighted by the probability of reaching that state-action pair:

$$\begin{aligned} \mathcal{V}^\pi(s) = & \sum_a \sum_{s'} \pi(a|s) \mathcal{T}_{ss'}^a \mathcal{R}_{ss'}^a \\ & + \sum_a \pi(a|s) \sum_{s'} \mathcal{T}_{ss'}^a \sum_{a'} \pi(a'|s') \sum_{s''} \mathcal{T}_{s's''}^{a'} \mathcal{R}_{s's''}^{a'} \\ & + \dots \end{aligned} \quad (13)$$

Letting $[\mathbf{P}]_{as, s'} = \sum_a \pi(a|s) \mathcal{T}_{ss'}^a$ be the effective transitions when following policy π , we can rewrite this as

$$\begin{aligned} \mathbf{V}^\pi &= \mathbf{R} + \mathbf{P}\mathbf{R} + \mathbf{P}^2\mathbf{R} + \dots \\ &= (\mathbf{I} - \mathbf{P})^{-1}\mathbf{R} \end{aligned} \quad (14)$$

where $[\mathbf{R}]_s$ is the first sum in Eq. 13 above. That is, the values of the states are linear in the immediate rewards $\mathbf{R}$, with the weights given by $\mathbf{I} + \mathbf{P} + \mathbf{P}^2 + \mathbf{P}^3 + \dots = (\mathbf{I} - \mathbf{P})^{-1}$, which is the total time spent in each state-action pair.

The strengths of model-based and model-free computations can also be combined to offset their mutual weaknesses. In Dyna-Q (Sutton 1990), samples as in Eq. 9 are generated from the agent’s internal estimates of $\mathcal{T}$ and $\mathcal{R}$ to updating model-free values. Conversely, model-free state values can be substituted for subtrees to reduce the size of decision trees (e.g., Campbell et al. 2002).

If the states $\mathcal{S}$ are not fully observable, the problem becomes a partially observable MDP (Kaelbling et al. 1998), which presents substantial additional complexities.

Behavior

Model-based and model-free accounts of behavior were held to be incompatible for much of the last century (Hull 1943; Tolman 1948). However, key signatures of both systems can be discerned within individual animals’ (Balleine and Dickinson 1994; Killcross and Coutureau 2003; Yin et al. 2004, 2005) and humans’ (Valentin et al.

2007; Daw et al. 2011) behavior and neurobiology. These signatures reflect central differences in their utilization of information. For a discussion, see Daw et al. (2005), Dayan and Berridge (2014), and Huys et al. (2014). This is also evidence for the use of the successor representation in humans (Russek et al. 2017; Momennejad et al. 2017).

In instrumental paradigms, particular actions a are reinforced in the presence of certain stimuli or in situations s . These experiments are modelled using $Q(a, s)$ values. In Pavlovian paradigms, stimuli s lead to reinforcements independent of subjects' actions. These paradigms are modelled using stimulus values $\mathcal{V}(s)$. Importantly, there can be model-based and model-free versions of both, leading to a quartet of values $\mathcal{V}^{\text{MF}}(s)$, $\mathcal{V}^{\text{MB}}(s)$, $Q^{\text{MF}}(s, a)$ and $Q^{\text{MB}}(s, a)$. Both model-free values $\mathcal{V}^{\text{MF}}(s)$ and $Q^{\text{MF}}(s, a)$ are *scalar* representations that change *slowly*. These two features account for its key behavioral signatures (Fig. 2).

The consequences of the *scalar* nature of model-free values are most clearly seen in Pavlovian scenarios, where $\mathcal{V}^{\text{MF}}(s)$ reflect only the magnitude of reinforcements but not other aspects such as whether an action was rewarded by food or water. One paradigmatic example is blocking experiments (Kamin 1969). In these, learning the reward association of a stimulus “B” in a compound “AB” is prevented if “A” already fully predicts the reward. Then the reward is fully

predicted; no prediction error occurs. Hence, model-free values are not updated and hence no learning occurs. Thus, if the model-free system makes no prediction about certain aspects of stimuli, then shifts in these aspects should not lead to learning. In transreinforcer blocking, animals treat a reward reduction and delivery of a shock punishment as equivalent (Dickinson and Dearing 1979), arguing for a linear and unitary representation of rewards and punishments as encapsulated in the single value r in Eq. 11. In Pavlovian unblocking, animals similarly can show an insensitivity toward shifts between rewards of equal magnitude but different modality (e.g., water and food; McDannald et al. 2011), showing that only the reward value, but not its other sensory features, is encoded. As a scalar value, model-free values can, however, replace reinforcements and be approached (if positive; Dayan et al. 2006) or avoided (if negative; Guitart-Masip et al. 2011). In conditioned reinforcement experiments, behavior is motivated by stimuli associated with the rewards (i.e., having positive model-free value $\mathcal{V}^{\text{MF}}(s)$) even in the absence of the rewards themselves (Bouton 2006). This can be captured by Actor-Critic models (Barto et al. 1983). By the same argument, model-free state or stimulus values $\mathcal{V}^{\text{MF}}(s)$ can also influence the vigor with which ongoing actions are performed (Pavlovian-instrumental transfer; Huys et al. 2011). These

Reward-Based Learning, Model-Based and Model-Free, Fig. 2 Early experiment used to argue that rats can build and use spatial representations. Figure after Tolman (1948). (a) Rats were first trained to find a food source located below the green point (a light). (b) After training,

the rats were placed in the same starting position at the bottom of the maze but found their usual route blocked. Instead, they now had multiple alternative arms they could run down. (c) Histogram of arm the rats chose to run down first

Reward-Based Learning, Model-Based and Model-Free, Fig. 3 Devaluation experiments. (a) Animals are first reinforced to press a lever for a particular food for either a brief period of time or for a long period. This food is then devalued, either by satiation or by pairing with illness. Animals are then given the opportunity to press the lever again, though in the absence of any food

outcomes (in extinction). (b) After brief initial training, animals will refuse to press the lever (green bar), but after extensive training, they will press the lever (purple bar) at the same rate as at the end of training (blue bar) despite refusing to consume the food if given the opportunity. (Figure adapted from Balleine and Dickinson 1994)

three features are also central to the notion of incentive value (McClure et al. 2003).

Model-free values change slowly over time as they rely on iterative updating (Eqs. 7 and 11). The consequences of this have been mainly examined in instrumental settings (though see Schoenbaum et al. 2009; Robinson and Berridge 2013 for Pavlovian examples). The paradigmatic example is outcome devaluation (Fig. 3). On the very first trial after the devaluation, the model-free system would have had no opportunity to update the $Q^{\text{MF}}(s, a)$ values via prediction errors δ and hence would predict continued responding. Conversely, by considering the now undesired outcome of actions, model-based evaluation should lead to a reduction in lever pressing on the very first trial after the devaluation. Accounts of the shift from early model-based and goal-directed to later model-free and habitual behavior rely on their statistical properties (Daw et al. 2005) or the tradeoff between the cost of cognition and the value of improved choices (Keramati et al. 2011).

Neurobiology

The component of model-free learning best understood is the representation of the temporal

prediction error δ . Interpreting earlier work by Schultz and Romo (1990) and Montague et al. (1996) pointed out that the phasic firing of dopaminergic midbrain neurons corresponds closely to the positive portion of the prediction error δ . This has been extensively validated with single-electrode recordings (even in humans; Zaghoul et al. 2009), functional neuroimaging (D'Ardenne et al. 2008), cyclic voltammetry (Day et al. 2007), with optogenetic manipulations (Steinberg et al. 2013) and in diseases of the dopamine neurons (Frank et al. 2004). This is true both in Pavlovian (Waelti et al. 2001; Flagel et al. 2011) and instrumental scenarios (Morris et al. 2006; Roesch et al. 2007). These phasic prediction errors are not just a linear reflection of the magnitude and probability of the expected reward (Tobler et al. 2005; Bayer and Glimcher 2005) but also of the summed long-term future rewards (Schultz et al. 1997; Enomoto et al. 2011). Dopamine neurons have a low-firing baseline and therefore appear to represent the negative portion of the prediction errors δ by the length of the pause in firing (Bayer et al. 2007). Phasic firing covaries with the development of behavioral responses (Waelti et al. 2001; Flagel et al. 2011) and can causally drive learning

(Steinberg et al. 2013; Saunders et al. 2018). Furthermore, pharmacological manipulations of dopamine alter the behavioral expression of model-free vs model-based behaviors (Nelson and Killcross 2006; Wunderlich et al. 2012).

In comparison, the neural location where prediction errors are summated into model-free values is much less well understood, although multiple parts of the affective neural circuitry appear to be involved, from the ventral (Cardinal et al. 2002; Corbit and Balleine 2011; McDannald et al. 2011) and dorsal portions of the striatum (Yin et al. 2004, 2005), the ventromedial prefrontal cortex (Killcross and Coutureau 2003; Smith and Graybiel 2013), to the amygdala (Corbit and Balleine 2005).

Similarly, the neural bases of the model-based system are also poorly understood. Depending on the nature of the structure represented in $\mathcal{T}$, different neural substrates will be required. Hence, there is a priori no reason to expect a unitary representation of a single model-based system. However, particular features of the system can probably be pinpointed. For instance, learning about a stimulus-stimulus transition matrix recruits the posterior parietal cortex (Gläscher et al. 2010), while model-based expectations of stimulus value involve the ventromedial prefrontal cortex (Hampton et al. 2006; Schoenbaum et al. 2009). Recordings from spatial navigation tasks in the rodent hippocampus are so far unique in yielding direct neural evidence of the implementation of sequential tree search (Johnson and Redish 2007; Pfeiffer and Foster 2013).

Psychopathology

Given the representation of a key model-free component by dopaminergic neurons, pathological excesses of dopamine have been suggested to involve a shift from model-based toward model-free decision-making (Redish et al. 2008; Robbins et al. 2012; Huys et al. 2014). This has been clearly demonstrated in laboratory animals (Dickinson et al. 2000; Nelson and Killcross 2006), though data in humans has been less clear-cut (Voon et al. 2015; Sebold et al. 2017; Nebe et al. 2017). Similar arguments have been made about other disorders with a striatal component, particularly obsessive-

compulsive disorders (Gillan et al. 2011, 2016), and models incorporating additional neurobiological details about the striatum can account for some of the choice patterns seen in Parkinson's disease, ADHD, and Tourette's (Maia and Frank 2011).

Definition

Early in development, vertebrate neural networks become spontaneously active in the absence of sensory inputs. Their activity is episodic and differs from the activity that will take place in the fully mature, functional network. In the isolated chick spinal cord preparation, episodic activity starts at embryonic day (E) 4 and lasts about 10 days. At E4, it is characterized by one short bout of synchronous activity along the ventral spinal cord occurring every 2 min. By E10, episodes can last over a minute and are comprised of several cycles of activity. Many different developing networks also produce episodic activity; this activity plays an important role in the maturity of the synaptic networks in which it is expressed (Blankenship and Feller 2010; O'Donovan 1999).

Detailed Description

Spontaneous network activity was first observed behaviorally as embryonic motility (Preyer 1937). This spinally generated activity occurs in bouts separated by periods of quiescence. Experimental isolation of the chick spinal cord for experimental studies was an important step in understanding the mechanisms that generate spontaneous episodic activity. The activity produced by the spinal cord *in vitro* resembles the activity observed *in ovo* but is more regular (Fig. 1).

In the functionally mature spinal cord of lamprey and *Xenopus* embryos, highly organized motor circuits (► [Rhythm Generation in Young *Xenopus* Tadpoles](#)) produce rhythmic activity

patterns thanks to “pacemaker” (oscillatory) neurons or reciprocal synaptic inhibition between groups of neurons. In the embryonic chick spinal cord, however, no particular circuit architecture is necessary to generate rhythmic episodes (Ho and O'Donovan 1993). Episodic activity is not dependent on pacemaker cells, and synaptic connections are all functionally excitatory at these early stages of development (Chub and O'Donovan 1998). This purely excitatory connectivity generates episodes of activity, which are thought to terminate due to an activity-dependent decrease in synaptic strength, which then recovers in the interepisode interval (Fedirchuk et al. 1999). The model described below shows that excitatory connectivity with slow synaptic depression can reproduce realistic episodic activity.

A Model of the Mean Network Activity

Because connectivity pattern appears to be unimportant, and because neurons are all active together, we only consider the average network activity, a (Fig. 2).

The equation describing the variations of activity is

$$\tau \frac{da}{dt} = -a + a_{\infty}(w s a - \theta_0)$$

where a_{∞} is a sigmoidal input/output function, continuously increasing from 0 (all neurons are silent) to 1 (all neurons are active). Parameter w measures network connectivity and θ_0 represents the amount of input necessary to make half the neurons active. This equation means that activity will reach a_{∞} with a time constant τ_a that sets the timescale for network integration of synaptic inputs. The term $w s a$ represents positive feedback with gain $w s$, due to the excitatory connections that inject activity back as input to the network (Fig. 2). Finally, s is a slow variable (timescale minutes) that represents activity-dependent synaptic depression. When activity is high, s decreases so the positive feedback gain is reduced. Variations of s are described by

Rhythm Generation in Embryonic Chick Spinal Cord,

Fig. 1 Spontaneous motor activity in developing chick. **(a)** Electrical activity recorded in ovo from a muscle. The activity occurs in bouts. **(b)** Electrical activity recorded from an E8 spinal cord *in vitro*. Activity episodes occur regularly

Rhythm Generation in Embryonic Chick Spinal Cord,

Fig. 2 Model structure. **(a)** Neurons are active together, but with different spike times, so their averaged activity (*bottom trace*) is a good indicator of global activity. **(b)** Activity as network output is injected back into the network due to the recurrent connectivity (shown in **a**). The gain of this positive feedback loop is $w s$

$$\tau_s \frac{ds}{dt} = -s + s_\infty(a)$$

where s_∞ is a decreasing function of a and $\tau_s \gg \tau_a$. One synaptic depression process operating on the minute timescale of s is the extrusion of Cl^- ions from neuronal somas and dendrites during episodes of activity (Chub and O'Donovan 2001; Marchetti et al. 2005). Cl^- extrusion weakens synaptic strength by decreasing postsynaptic excitatory currents.

The model described by these two equations can produce episodic activity with slow oscillations of s controlling the transitions between high and low activity. When activity is high, synapses depress so s goes down, until it becomes too low to sustain activity. The network then becomes silent, allowing synapses to recover. When s becomes high enough, activity jumps up to a high level and the cycle continues (Fig. 3a).

Rapid cycling during an episode can be modeled by adding another synaptic depression variable, d , that varies on a timescale of hundreds of milliseconds – slower than a , but much faster than s . Synaptic depression on this timescale may represent neurotransmitter depletion at synaptic terminals. The full model with both fast and slow synaptic depression produces spontaneous episodes of rhythmic activity as shown Fig. 3b (Tabak et al. 2000).

Models Based on Individual Spiking Neurons

The model described above captures essential features of spontaneous episodic activity, on the network scale and on a coarse-grained timescale. Episodic activity in excitatory networks with synaptic depression has also been investigated with network models that incorporate many neurons connected to each other (Tsodyks et al. 2000; Vladimirovski et al. 2008; Wiedemann and Luthi 2003). These models allow observing the activity of individual neurons in the network and incorporate the effects of stochastic spike timing. Connecting all the individual neurons produces “population spikes,” or bursts, during which most neurons are active, separated by periods of quiescence. One common feature of these models is that the neurons in the networks have different excitability levels. Some spike spontaneously most of the time, while most are silent unless they receive sufficient synaptic inputs. This heterogeneity of neuronal properties allows the network to produce robust episodic activity.

Excitatory network models with some form of activity-dependent negative feedback (synaptic depression or neuronal refractoriness) also describe episodic activity in other developing networks, such as the retina (Butts et al. 1999), or population bursts in hyperexcitable hippocampal networks (Staley et al. 1998).

Rhythm Generation in Embryonic Chick Spinal Cord,

Fig. 3 Episodic activity generated by the model. **(a)** The model generates periods of high activity during which synapses slowly depress (s decreases). After the activity

stops, synapses recover (s increases) until the next episode begins. **(b)** With an additional, fast, synaptic depression variable, rhythmic cycling occurs during the episodes of activity

Model Achievements

The models have demonstrated that rhythmic episodes of activity can be generated according to a simple mechanism requiring only excitatory connections and activity-dependent depression. They also explain two important sets of data.

Blocking excitatory neurotransmission abolishes activity in most neural networks. In the embryonic spinal cord, pharmacological blockers of receptors for the neurotransmitters acetylcholine and glutamate abolish spontaneous activity for up to 3 h, but after this delay activity reappears with similar characteristics as before pharmacological block (Chub and O'Donovan 1998). Why does activity recover in the presence of the synaptic blockers?

This can be explained with our mean activity model, where parameter w represents the total synaptic connectivity comprising glutamatergic, cholinergic, and GABAergic/glycinergic synapses. Blocking glutamatergic synapses is equivalent to decreasing w . If we decrease w by a small amount, the model also stops generating activity for a long period, but eventually activity reappears as it was before decreasing w (Fig. 4). When w is

decreased, the gain of the positive feedback loop, $w s$, decreases too, so the model can no longer be active. During the long period of inactivity, s increases to higher than normal level and compensates for the decreased w . Activity thus resumes with $w s$ operating at its normal range thanks to s operating at a higher level. This suggests that the GABAergic/glycinergic connections become stronger to compensate the block of the glutamatergic connections.

This model prediction was confirmed experimentally when it was shown that GABAergic responses were larger after glutamatergic blockade (Tabak et al. 2001). Therefore, the synaptic depression process responsible for the episodic nature of the activity also provides the plasticity that allows this activity to be robust to disruptions in synaptic connectivity. Such homeostatic plasticity has since been further investigated in the developing chick spinal cord in ovo (Gonzalez-Islas and Wenner 2006; Wilhelm and Wenner 2008).

One surprising experimental finding that also results from synaptic depression controlling the occurrence of activity episodes is that the duration of an episode strongly depends on the length of the *preceding* silent interval, but does not affect

Rhythm Generation in Embryonic Chick Spinal Cord, Fig. 4 Blockade experiment. **(a)** Upper trace, blocking glutamatergic synaptic transmission stops the activity for a long period of time, but then the activity resumes with similar characteristics as control activity. Lower panel

shows the interepisode intervals. **(b)** Model behavior when the connectivity parameter w is decreased to mimic glutamatergic blockade. As in the experiments, activity eventually resumes and interepisode intervals are slightly longer than control intervals

Rhythm Generation in Embryonic Chick Spinal Cord,

Fig. 5 Correlation pattern in spontaneous activity. (a) Spontaneous activity recorded from an E10 chick spinal cord. (b) There is a clear correlation between episode duration and the length of the preceding, but not following, interepisode interval. (c) This suggests that network excitability at episode onset is variable but always reaches the same value at episode termination

the length of the *following* interval (Fig. 5; Tabak et al. 2001). This suggests that the network is always in the same state at the end of an episode. Such pattern has also been found in many developing or hyperexcitable networks (O'Donovan 1999).

The models based on a heterogeneous population of spiking neurons produce the same strong correlation between episode duration and the preceding, but not following, interval. This correlation pattern is not affected if we change the average number of connections in the network or the properties of the single cells, demonstrating that it is a robust feature of excitatory networks with synaptic depression (Tabak et al. 2010). That such robust correlation pattern can be obtained using simple network models and the fact that many developing networks produce this pattern provide evidence that neural networks that differ widely, such as the spinal cord and the retina, operate using similar principles early in their development.

Rhythm Generation in Young *Xenopus* Tadpoles

Alan Roberts
School of Biological Sciences, University of
Bristol, Bristol, UK

Synonyms

[Behavior of just-hatched frog tadpoles and the neuronal networks underlying it](#)

Definition

Just after they hatch from the egg, tadpoles of the frog *Xenopus* can swim when touched and make stronger struggling movements when

held. They provide one of the simplest organisms where the networks' underlying behavior can be studied. Models of swimming networks rely on the interaction of pacemaker and network rhythm generation based on reciprocal inhibition and rebound. The network can be reconfigured during continuous stimulation when some neurons active during swimming become silent and new neurons are recruited, so the network generates the slower struggling pattern.

Detailed Description

Background

The spinal cord of the adult mammal has proved very difficult to investigate and understand. This is the reason to look for simpler, related systems which might be more accessible. The hatchling frog tadpole is a vertebrate like us, but its nervous system has only just begun to generate the behavior needed for survival. The inspiration for studying it came from the simple network diagrams in a book by George Coghill (1929) on the development of the brain and behavior of tiger salamander tadpoles. I chose *Xenopus* to study the sensory systems controlling behavior (Roberts 1969) because tadpoles can be obtained throughout the year. They have two main responses (Roberts et al. 2010): when touched, they bend their trunk and swim away (15–25 Hz with head-to-tail waves) and when grasped by a predator, they struggle violently (5–10 Hz with tail-to-head waves). The neurons controlling responses have been studied in immobilized tadpoles, first with sharp microelectrodes and dye filling and more recently using whole-cell recordings with neurobiotin. The skin is stimulated electrically to evoke responses monitored with electrodes on the motor nerves going to the trunk muscles. This work has led to a remarkably detailed picture of the anatomy and physiology of the ten or so types of neuron in the spinal cord and hindbrain which control the tadpole's responses to skin stimulation. This entry outlines modeling studies of the tadpole networks.

Modeling Swimming

From an early stage in the investigation, network modeling was used to evaluate ideas about how swimming was generated. The pattern of spinal neuron firing during swimming is very simple with each neuron type firing only once on each cycle. There was no evidence of any neurons firing at high rates to produce a steady excitatory drive to turn on swimming. However, the *Xenopus* tadpole was the place where long-duration, NMDAR-mediated glutamate excitation was first discovered (Dale and Roberts 1985). This led to the hypothesis that rhythmic activity is sustained after a brief stimulus by feedback excitation on each cycle from the excitatory neurons driving swimming. These neurons fire a single spike, but their excitation has a time course longer than the swim cycle period and so can sum from cycle to cycle to sustain rhythmic firing (Roberts et al. 1984). The second hypothesis was that the basic alternating swimming rhythm is produced by a post-inhibitory rebound mechanism (Perkel and Mulloney 1974) similar to that found in the swimming network of the marine snail *Clione* (Satterlie 1985). In the tadpole, such rebound firing did not occur at rest but could lead to firing in neurons held depolarized by the slow NMDA component of glutamate excitation and receiving mid-cycle reciprocal inhibition from glycinergic neurons on the opposite side of the spinal cord (Soffe 1990). Modeling showed that networks, where the excitatory neurons had appropriate properties based on the evidence from recordings, could generate swimming based on post-inhibitory rebound (Roberts 1989; Roberts and Tunstall 1990; Tabak and Moore 1998).

Whole-cell recordings from spinal neurons led to new ideas about the role of the spinal excitatory neurons active during swimming. Dale proposed that these neurons acted as pacemakers to drive swimming and that the single firing responses to current injections seen with sharp microelectrodes were artifacts resulting from damage-induced leak currents (Aiken et al. 2003; Dale 1995a, b, 2003). However, later in situ whole-cell recordings showed that this was not the case and built up a very complete picture of the

neurons and synaptic connections underlying swimming (Li 2011; Wolf et al. 1998). This allowed evidence-based modeling of the swimming network and confirmed that the post-inhibitory rebound mechanism could produce stable rhythm (Sautois et al. 2007). The large number of paired recordings also suggested that synaptic contacts could be made probabilistically and modeling showed that networks built on this principle could swim (Li et al. 2007a). A crucial discovery was that the excitatory neurons driving swimming were switched into pacemaker mode when their mutual synapses activated NMDARs (Li et al. 2010). This finding could explain the rhythm generation found in a single isolated side of the CNS and reconcile the earlier proposals made by Dale (1995a). Our current modeling is investigating the significance of these pacemaker properties in the population of electrically coupled excitatory neurons.

During swimming motor activity starts in the rostral trunk and spreads toward the tail, and recordings have shown that there is a head-to-tail gradient in the excitation and inhibition underlying swimming (Tunstall and Roberts 1991, 1994; Zhao et al. 1998). The tadpole like other biological networks has long-range axonal coupling so cannot be treated as a series of oscillators with nearest neighbor coupling. Modeling has shown that gradients in synapse numbers can be generated when neurons with relatively short axons are unevenly distributed along the nervous system (Wolf et al. 2009): with more neurons near the head, there are more synapses. Gradients in synapse numbers can lead to head-to-tail propagation of activity during swimming. The detailed synaptic mechanisms coupling activity longitudinally have been investigated (Tunstall et al. 2002).

Modeling Struggling

Struggling is a slower pattern of activity where motor neurons fire bursts of spikes like those seen during locomotion in most larger animals. Unlike swimming, this means that burst termination mechanisms are required. Struggling occurs when the tadpole is grasped or during continuous skin stimulation (at 25–40 Hz) (Soffe 1991) and involves the recruitment of additional reciprocal

inhibitory neurons and motoneurons (Soffe 1993). Whole-cell recordings with neurobiotin injections later revealed new types of neurons only recruited during struggling (Li et al. 2007b), but when the network was modeled, alternating bursting was unstable. This led to the discovery that reciprocal inhibition was antifacilitated at struggling intra-burst frequencies. When this process was included in the model as a burst termination mechanism, stable struggling activity could be obtained. The mechanisms for tail-to-head propagation of the struggling wave have not yet been elucidated.

Rhythm Perception: Pulse and Meter

Edward W. Large

Department of Psychology, University of Connecticut, Storrs, CT, USA

Synonyms

Beat, Dynamic attending, Metrical structure, Neural oscillation, Neural resonance, Rhythmic entrainment

Definition

Pulse and *meter* are perceptual/attentional responses to patterns of timing and stress in acoustic rhythms. Pulse corresponds to the perception of periodicity, while meter corresponds to the perception of alternating strong and weak beats. Pulse and meter are thought to arise as cortical rhythms entrain to acoustic rhythms, influencing temporal expectancy and attention. Computational models of pulse and meter as neural resonance to acoustic rhythms are based on theoretical models of neural oscillation.

Detailed Description

Musical rhythm is of considerable interest as a model system for the study of rhythmic communication. In music, rhythms are often perceived to have a pulse or basic beat in the approximate range of 0.5–4 Hz (London 2004). Meter corresponds to the percept of alternating strong and weak beats (Lerdahl and Jackendoff 1983) and, metrical structures include the pulse frequency, slower beat frequencies (<2 Hz) that group pulse cycles and higher beat frequencies that subdivide the pulse (4–8 Hz) (London 2004). Metrical structures are stereotypical patterns that can be described in terms of phase and frequency relationships among multiple frequency components. Frequency relationships are theoretically restricted to harmonics (e.g., 1:2, 1:3),

subharmonics (e.g., 2:1 and 3:1), and other simple integer ratios (e.g., 3:2, 4:3) (London 2004). Rhythmic patterns also group into phrase structures (see Fig. 1). Speech is generally hierarchical as well syllables (4–8 Hz) assemble into lexical and phrasal units at slower timescales (<4 Hz) (Giraud and Poeppel 2012). However, the fundamental temporal structures of speech are more flexible and less well understood than those of music.

Neural Resonance

Pulse and meter are believed to arise as endogenous cortical rhythms entrain to acoustic rhythms. Entrainment of cortical rhythms to music and speech is thought to engage neurodynamic mechanisms of temporal prediction and attention (Large and Jones 1999) and segregate incoming information (Ghitza 2011). Auditory cortical rhythms, for example, nest hierarchically (Lakatos et al. 2005) and are entrained by music and speech rhythms. Acoustic stimulation in the range of musical pulse synchronizes cortical rhythms in the delta band (e.g., Will and Berg 2007; Nozaradan et al. 2011), and stimulation with spoken syllables synchronizes cortical rhythms in the theta band (e.g., Luo and Poeppel 2007). In general, the neural resonance theory of pulse and meter holds that neural oscillations in distributed cortical and subcortical areas entrain to the rhythms of auditory sequences (Large 2008).

Models of Pulse and Meter

Generic models of neural oscillation are often used for modeling pulse and meter because they make predictions that hold under a rather general set of assumptions. Equation 1, for example, is a generic model that can be derived from the Wilson-Cowan model of neural oscillation (Aronson et al. 1990; Large et al. 2010):

$$\frac{dz}{dt} = z(\alpha + i\omega + (\beta + i\delta)|z|^2) + c s(t) + \text{h.o.t.} \quad (1)$$

Rhythm Perception: Pulse and Meter, Fig. 1 Musical rhythm, pulse, meter, and grouping. Piano score of Isaac Albeniz's *Iberia II, Triana*, annotated with pulse (black dots), metrical structure (all dots), and phrasing (brackets). Pulse frequencies overlap with cortical

oscillations in the delta range, while other metrical frequencies extend into theta and sub-delta ranges. Frequency relationships among metrical levels are restricted to harmonics, subharmonics, and other integer ratios

This differential equation is two dimensional, because z is a complex variable, having real ($Re(z)$) and imaginary ($Im(z)$) parts. It has both real (α , β) and imaginary (ω , δ) parameters as well, whose meanings are described next. In neural oscillator models of pulse and meter, the system is driven by a temporal sequence, $s(t)$, of event onsets as illustrated in Fig. 2a.

When this system is driven with an external rhythm, an oscillation may arise (e.g., Fig. 3a) and entrain to the stimulus. To study this behavior, Eq. 1 is rewritten in polar coordinates, by setting $r = e^{i\phi}$ (Fig. 3b), revealing the dynamics of amplitude, r , and phase, ϕ , individually:

$$\begin{aligned} \frac{dr}{dt} &= r(\alpha + \beta r^2) + cs(t) \cos \phi + \text{h.o.t.} \\ \frac{d\phi}{dt} &= \omega + \delta r^2 - c \frac{s(t)}{r} \sin \phi + \text{h.o.t.} \end{aligned} \quad (2)$$

The parameters relate directly to the amplitude and phase of the oscillation. They are α , the bifurcation parameter; β , the nonlinear saturation parameter; ω , the natural frequency ($\omega = 2\pi f$, f in Hz); and δ , a detuning parameter (for details, see Large (2008)). The connection strength, c ,

captures the influence of the stimulus on the oscillator.

Neurodynamic models assume that neural oscillations in the range of musical pulse entrain to the stimulus sequence, as do oscillations at higher and lower metrical frequencies. Entrainment in integer-ratio-structured patterns is based on mode-locking, a generalization of phase-locking in which a periodic stimulus interacts with an intrinsic oscillatory dynamics of a neuron or neural circuit, causing k cycles of an oscillation to lock to m cycles of the stimulus, where k and m are integers (in phase-locking $k = m = 1$). In Eqs. 1 and 2, mode-locking neural dynamics are captured in the higher-order terms (h.o.t.). For an expansion of higher-order terms that captures mode-locking, see Large et al. (2010). This article explains mode-locking using a discrete-time model, next.

Discrete-Time Models

If a neural oscillator spontaneously generates an oscillation with a stable limit cycle amplitude, and

Rhythm Perception: Pulse and Meter, Fig. 2 Driving rhythms. Input to a neural oscillator model of pulse/meter is assumed to be a temporal sequence of event onsets. (a) Continuous-time onset sequence (Eq. 1, $s(t)$). (b) Discrete-time representation (Eq. 5, t_n)

Rhythm Perception: Pulse and Meter, Fig. 3 Canonical neural oscillation. (a) When stimulated at an appropriate frequency, a neural oscillation arises and entrains to a musical rhythm. The point in the cycle when $Re(z) = 0$ is usually assumed to correspond to an individual beat or pulse (see Fig. 1). (b) The oscillation can also be understood in terms of amplitude, r , and phase, ϕ

the stimulus is not too strong, then we can ignore amplitude and work entirely in the phase dimension (Pikovsky et al. 2001). We consider the phase equation of the system above, ignoring frequency detuning and higher-order terms:

$$\frac{d\phi}{dt} = \omega - c s(t) \sin \phi \tag{3}$$

Next, assume the stimulus to be a periodic series of discrete impulses with fixed period, T_0 (T_0 (sec) = $1/f_0$ (Hz); note also, $\omega_0 = 2\pi f_0$). Then the above phase equation can be integrated to create the discrete-time (stroboscopic) mapping.

$$\phi_{n+1} = \phi_n + \omega T_0 - c \sin \phi_n \tag{4}$$

known as a circle map (Pikovsky et al. 2001; Glass 2001). Formally, one should also apply the operation modulo 2π to the right-hand side, but it is omitted here for simplicity of presentation. Once this transformation has been accomplished, ϕ represents relative phase, the phase of the oscillator when an input event occurs. The discrete-time model exhibits phase-locking and mode-locking properties that make it useful for describing structural aspects of pulse and meter (Large and Kolen 1994; McAuley 1995).

Phase-Locking and Mode-Locking

Figure 4 shows resonance regions called Arnol'd tongues, based on simulation of Eq. 4 (cf., Glass 2001). Figure 4 illustrates that a neural oscillator locks to stimuli near its own frequency and to integer-ratio-related frequencies. Importantly, oscillations lock at frequencies that are not present in the stimulus. The most stable response is found at the stimulus frequency (i.e., 1:1 phase-locking), but mode locks are also observed at harmonics (e.g., 2:1), subharmonics (e.g., 1:2 and 1:3), and integer multiples (e.g., 3:2). At low coupling strengths, mode-locking regions are small; they

increase with coupling strength. Phase- and mode-locking capture many aspects of pulse and meter that have been directly observed in experiments (Large 2008).

Discrete-Time Models of Pulse

To create a discrete-time model that can handle complex musical rhythms, it is assumed that a sequence of event onsets (Fig. 2a) may be described as temporally discrete impulses (Fig. 2b). Such data is readily collected in the laboratory in the form of MIDI recordings of musical performances and retains the most basic information about event timing. The key insight is to replace the fixed period, T_0 , of a discrete map with the succession of event times in a music performance:

$$\phi_{n+1} = \phi_n + \omega(t_{n+1} - t_n) - cF(\phi_n) \quad (5)$$

This formulation was conceived as a model of temporal expectation by Large and Kolen (1994) and as a model of dynamic attending (Large and Jones 1999). According to McAuley (1995), the basic theoretical insight is to model the perception of time as phase. Related models, termed adaptive

Rhythm Perception: Pulse and Meter,

Fig. 4 Mode-locking regions for Eq. 4. Arnol'd tongues show where mode locks occur, depending on the parameter c and the relative frequency, ω/ω_0 ($\omega_0 = 2\pi/T_0$). A few of the larger, more stable mode locks are labeled

oscillators, include adaptation of oscillation frequency (or equivalently, period).

Role of Delayed Feedback in Human Balancing

Tamas Insperger¹ and Gabor Stepan²

¹Department of Applied Mechanics, Budapest University of Technology and Economics and MTA-BME Lendület Human Balancing Research Group, Budapest, Hungary

²Department of Applied Mechanics, Budapest University of Technology and Economics, Budapest, Hungary

Definition

The destabilizing effect of reaction delay to balancing tasks is demonstrated using the pendulum-cart (inverted pendulum) model associated with delayed proportional-derivative (PD) feedback.

Detailed Description

Stabilization of unstable equilibria and orbits by means of feedback control is a highly important task in engineering and science. It is more efficient to start quick movements from an unstable position than from a stable one, while the energy

demand of the control process is relatively small. Maintaining balance is also a vital ability for humans: falls are leading causes of accidental death and morbidity in the elderly, which provides a strong motivation to understand the nature of mechanisms that maintain human balance, why these mechanisms fail, and how risks for falling can be minimized. The primary causes that deteriorate the performance of feedback control systems are reaction delay and sensory uncertainties.

Here, the basic model of balancing is presented, where the control law is a delayed proportional-derivative (PD) feedback. It is shown how the feedback delay deteriorates the stability properties of the control process. A model of stick balancing on the fingertip is investigated, but the underlying mathematical model is similar to postural sway, too.

Mechanical Model

Experiments on stick balancing on the fingertip (Milton et al. 2016) show that in most of the cases (72% for novice stick balancer and 84% for experienced stick balancers), stick falls in the AP direction, which can be explained by the necessity of depth perception for the estimation of the spatial angular position of the stick. Balancing trials also show that the movements of the arm of the stick balancer are confined to the elbow and shoulder while the wrist and finger are held rigid and moved horizontally (Cabrera and Milton 2004;

Lee et al. 2012; Milton et al. 2016). These observations imply that stick balancing on the fingertip in the AP direction can be modeled as a pendulum-cart system moved by a slider crank linkage, which models the human arm mechanism as shown in Fig. 1. This model can be reduced to a simple pendulum-cart system with an equivalent mass m_0 of the cart, which involves the inertia and the mass of the arm segments.

The equivalence of the models shown in panels B and C in Fig. 1 is to be established based on the equivalence of their kinetic energy. The kinetic energy of the arm mechanism can be given as

$$E_{\text{kin,arm}} = \frac{1}{2}m_u v_u^2 + \frac{1}{2}J_u \dot{\varphi}_u^2 + \frac{1}{2}m_f v_f^2 + \frac{1}{2}J_f \dot{\varphi}_f^2 + \frac{1}{2}m_h v_h^2, \quad (1)$$

where v_u , v_f , and v_h are the velocities of the center of gravity of the upper arm, forearm, and hand, respectively, and J_u and J_f are the moment of inertia with respect to the normal line via the center of gravity of the upper arm and the forearm. Assuming homogeneous arm segments, we have $J_u = \frac{1}{12}m_u \ell_u^2$ and $J_f = \frac{1}{12}m_f \ell_f^2$. The mass of the stick is negligible compared to the mass of the arm-hand mechanism (cart), and then the kinetic energy of the pendulum-cart model is

$$E_{\text{kin,car}} = \frac{1}{2}m_0 \dot{x}^2, \quad (2)$$

Role of Delayed Feedback in Human Balancing, Fig. 1 (a) Subject balancing stick on fingertip. (b) Slider crank model of the arm used to estimate the equivalent

mass of the cart for the pendulum-cart model. (c) Pendulum-cart model for stick balancing with equivalent mass

Role of Delayed Feedback in Human Balancing,
Table 1 Arm segment parameters taken from de Leva (1996)

Segment	Mass	Length (ℓ)
Upper arm	$m_u = 1.775$ kg	$\ell_u = 0.2874$ m
Forearm	$m_f = 1.015$ kg	$\ell_f = 0.2666$ m
Hand	$m_h = 0.395$ kg	$\ell_h = 0.0821$ m

where x is the displacement of the cart and $\dot{x}$ is its derivative with respect to time (i.e., the cart's velocity).

Using the equations $E_{\text{kin,arm}} = E_{\text{kin,cart}}$, $v_h = \dot{x}$ and the relations between the velocities v_u , v_f , and v_h and the angular velocities $\dot{\varphi}_u$ and $\dot{\varphi}_f$, one can calculate the equivalent mass m_0 of the cart. The parameters of the mechanism are set according to the average human arm segment as listed in Table 1 (de Leva 1996). Assuming $\varphi_u \approx 20$ deg, and $\varphi_u \approx 10$ deg. for the arm segment positions during stick balancing, the mass of the cart is obtained to be $m_0 = 2.46$ kg.

The pendulum-cart system can be modeled by a two-degree-of-freedom system governed by

$$\begin{pmatrix} \frac{1}{3}m\ell^2 & \frac{1}{2}m\ell\cos\theta \\ \frac{1}{2}m\ell\cos\theta & m+m_0 \end{pmatrix} \begin{pmatrix} \ddot{\theta} \\ \ddot{x} \end{pmatrix} + \begin{pmatrix} -\frac{1}{2}mg\ell\sin\theta \\ -\frac{1}{2}m\ell\dot{\theta}^2\sin\theta \end{pmatrix} = \begin{pmatrix} 0 \\ f(t) \end{pmatrix}, \quad (3)$$

where θ is the vertical displacement angle of the stick; m and m_0 are the mass of the stick and cart, respectively; ℓ is the length of the stick; $\ddot{x}$ is the acceleration of the cart (fingertip); and $f(t)$ describes the control force exerted at the fingertip. The linearized equation of motion is

$$\begin{pmatrix} \frac{1}{3}m\ell^2 & \frac{1}{2}m\ell \\ \frac{1}{2}m\ell & m+m_0 \end{pmatrix} \begin{pmatrix} \ddot{\theta} \\ \ddot{x} \end{pmatrix} + \begin{pmatrix} -\frac{1}{2}mg\ell & 0 \\ 0 & 0 \end{pmatrix} \begin{pmatrix} \theta \\ x \end{pmatrix} = \begin{pmatrix} 0 \\ f(t) \end{pmatrix}. \quad (4)$$

If the control force does not depend on x and $\dot{x}$, then x is a cyclic coordinate, which can be eliminated and the equation of motion can be reduced to

$$\ddot{\theta}(t) - \frac{6g}{c\ell}\theta(t) = -\frac{6}{(m+m_0)c\ell}f(t), \quad (5)$$

where the parameter $c = 4 - 3m/(m+m_0)$ is equal to 1 when $m_0 = 0$ and to ~ 4 when $m_0 \gg m$. The coefficient $6g/c\ell$ is often called system parameter since $\omega_n = \sqrt{6g/c\ell}$ is the angular natural frequency of the free pendulum hung downward. The corresponding oscillation period is

$$T = 2\pi\sqrt{\frac{c\ell}{6g}}. \quad (6)$$

The control force f is assumed to be a locally linear function of the angular position θ and the angular velocity $\dot{\theta}$ in the form

$$f(t) = K_p\theta(t-\tau) + K_d\dot{\theta}(t-\tau) + \text{h.o.t.}, \quad (7)$$

where K_p is the proportional gain, K_d is the derivative gain, τ is the reaction delay, and h.o.t. stands for the higher-order terms not modeled here. It shall be mentioned that the displacement x and its derivative $\dot{x}$ are not involved in the control law. This means that there is no limitation to translational motion in the model. However, in real experiments, there is a limitation, namely, the arm length when the subjects are performing the balancing task sitting on a chair or the length of the cart track when balancing a pendulum-cart system.

Finally the governing equation can be written in the simple form

$$\ddot{\theta}(t) - a\theta(t) = -k_p\theta(t-\tau) - k_d\dot{\theta}(t-\tau), \quad (8)$$

where

$$a = \frac{6g}{c\ell}, \quad (9)$$

$$k_p = \frac{6K_p}{(m+m_0)c\ell}, \quad (10)$$

$$k_d = \frac{6K_d}{(m + m_0)c\ell}. \quad (11)$$

Stability and Stabilizability

Stability properties can be given after the analysis of the characteristic roots λ (Insperger and Stepan 2011; Stepan 1989). For this, the characteristic function reads

$$D(\lambda) = \lambda^2 - a + k_p e^{-\lambda\tau} + k_d \lambda e^{-\lambda\tau}. \quad (12)$$

According to the D-subdivision method (Stepan 1989), substitution of $\lambda = \gamma \pm i\omega$, $\omega \geq 0$, into $D(\lambda) = 0$, decomposition into real and imaginary part, and setting $\gamma = 0$ give the D-curves in the form

$$\text{if } \omega = 0: k_p = a, \quad k_d \in \mathbb{R}, \quad (13)$$

$$\begin{aligned} \text{if } \omega \neq 0: k_p &= (\omega^2 + a) \cos(\omega\tau), \\ k_d &= \frac{\omega^2 - a}{\omega} \sin(\omega\tau). \end{aligned} \quad (14)$$

The D-curve $k_p = -a_0$ given by (13) is associated with a real critical characteristic exponent $\lambda = 0$. The D-curve given by (14) is associated with a complex conjugate pair of characteristic exponents of the form $\lambda = \pm i\omega$. In (14) $\omega \in [0, \infty)$ can be treated as a running parameter. For a fixed a , these curves cut the parameter plane (k_p, k_d) into infinitely many domains. In each of these

domains, the number of unstable characteristic roots is fixed. The stable domain (with zero unstable root) is the one attached to the point $(k_p, k_d) = (a, a\tau)$ (Insperger and Stepan 2011).

A series of stability diagrams are shown in Fig. 2 for balancing a stick of length $\ell = 0.25$ m with different reaction delays. It can be seen that the stable region shrinks with the reaction delay, and at a critical value τ_{crit} , it disappears. This means that if $\tau > \tau_{\text{crit}}$, then stabilization by delayed PD feedback is not possible. In case of a stick of length $\ell = 0.25$ m, one requires faster reactions than 184 ms.

It can be shown that the stable region disappears when the tangent of the parametric curve (14) at $\omega = 0$ becomes vertical. Analytical calculations give

$$\tau_{\text{crit}} = \sqrt{\frac{2}{a}}, \quad (15)$$

which can be reformulated as

$$\tau_{\text{crit}} = \frac{T}{\pi\sqrt{2}}, \quad (16)$$

where T is the period of the small oscillations of the structure hung at its downward position (Stepan 2009).

The same relation can be phrased in terms of the critical length. The critical length l_{crit} is a length of the pendulum that can be balanced by a

Role of Delayed Feedback in Human Balancing, Fig. 2 Number of unstable characteristic exponents for (8) with length $\ell = 0.25$ m and with different feedback delays τ

PD feedback with reaction delay τ . Substituting (9) into (15) gives

$$l_{\text{crit}} = \frac{3}{c} g \tau^2. \quad (17)$$

When balancing a stick made of wood on the fingertip, then typically $m \ll m_0$; hence $c \approx 4$. An average human reaction delay is somewhere between 200 and 250 ms. This gives that humans typically cannot balance sticks of length shorter than 30 ~ 46 cm, which agrees with the experimental observations (Milton et al. 2016).

Discussion

In the above analysis, delayed PD feedback was assumed. However, many other types of control concepts are investigated in the literature as possible candidate for the human control process. A trivial extension of PD feedback is the application of an integral term, hence PID feedback (Maurer and Peterka 2005). Addition of the I term however does not help in the stabilization process, i.e., the critical delay for a PID control is obtained when the integral gain is zero (Lehotzky 2017). When the acceleration is also fed back (PDA feedback), then the critical delay is increased by a factor of $\sqrt{2}$, which means that the critical length is reduced to half of that of the PD feedback (Insperger et al. 2013; Sieber and Krauskopf 2005). Delay compensation, when an internal model is able to predict the consequences of the control commands over the delay period, is also an often used control concept, which in control theory is called predictor feedback (Krstic 2009; Milton et al. 2016), while in the neuroscience literature, it is called forward model (Mehta and Schaal 2002). When the internal model is perfectly accurate, then the delay can be totally compensated. In theory, there is no limit to the size of the critical delay in this case. However, the internal model and its performance are never perfect, which introduces modeling error in the control process that presents further limitations to the balancing abilities. Other types of control concepts, such as intermittent predictive control

(Gawthrop et al. 2013), event-driven intermittent controller (Yoshikawa et al. 2016), and act-and-wait (Insperger 2006) or drift-and-act controllers (Milton et al. 2009) are also often used to model and explain human balancing performance.

Definition

The SenseLab project involves novel informatics approaches to constructing databases and Web-enabled applications for collecting, modeling, analyzing, and sharing neuroscience information. The emphasis of SenseLab (<http://senselab.org>) is

on building experimental data into integrated, multidisciplinary models of neurons and neural systems in order to gain insight into the neural basis of behavior. SenseLab is also part of the ► “Neuroscience Information Framework (NIF)” project and the International Neuroinformatics Coordinating Facility (INCF).

Detailed Description

SenseLab was founded in 1993 as part of the original Human Brain Project sponsored by the National Institutes of Health, National Science Foundation, and several other government funding agencies in the United States, which began the development of neuroinformatics tools in support of neuroscience research. Using the olfactory system as a model, SenseLab has built a suite of nine databases (see Fig. 1) to support research across multiple disciplines and at multiple scales of time and space. We test the validity and value of each database for its usefulness for our own research on synaptic organization and sensory processing and seek to develop principles for general application to other neural systems, as summarized in *The Synaptic Organization of the Brain* (Shepherd 2004) and *Handbook of Brain Microcircuits* (Shepherd and Grillner 2010).

SenseLab is built on three foundations. First is the informatics expertise provided by the Yale Center for Medical Informatics (<http://ycmi.med.yale.edu>). This was one of the first such centers in the United States, formed by Dr. Perry Miller in

the 1980s, and has enabled SenseLab to have state-of-the-art informatics as an integral part of our approach by providing the digital infrastructure for the experimental data and for the online databases. This has enabled the different SenseLab databases to be developed in a tightly interoperational framework.

Second are databases for neuroscience data and computational models. The aim is to provide curated published models to enable computational neuroscientists efficiently to run published models to check them and use them to apply to their own research. The importance of computational models for integrating neuroscience data was envisaged in the original Human Brain Project (see Pechura and Martin 1991). This approach is being supported by four interoperational databases, starting with a simple neuron inventory and working up through canonical neurons to neuron models and finally microcircuit models. This sequence starts with **CellPropDB**, a database of currents, neurotransmitter receptors, and neurotransmitters expressed in 30 types of neurons that can be searched across neurons (in parallel to Neurolex Neuron in the NIF). **NeuronDB** expands this to expression in different parts of the dendrites and axons of canonical neuron representations, enabling properties to be searched across neuronal compartments.

The quantitative integration of these properties occurs in the models contained in **ModelDB**. The modeling methods were introduced in neuroscience by Wilfrid Rall, with the first applications to brain neurons in the olfactory bulb (Rall and

SenseLab: Integration of Multidisciplinary Neuroscience Data, Fig. 1 Suite of databases in SenseLab

Shepherd 1968). Current studies rely widely on the modeling environment NEURON (Hines and Carnevale 2014). Dr. Michael Hines brought the NEURON simulation environment to SenseLab in 1995. ModelDB contains fully curated published models running in NEURON and over 50 other modeling programs, with functionality for searching for specific properties. The total number of entries is currently 801 models. Recently, **MicrocircuitDB** has been introduced to cover multineuronal circuits within specific brain regions. It currently contains 180 models for microcircuits in 24 brain regions.

In addition to these general neuron databases, SenseLab also supports research in the olfactory system with an extensive archive of properties related to the olfactory receptors. This is a particularly challenging task given that these receptors are the largest family in the genome (Buck and Axel 1991). The olfactory receptor database (**ORDB**) serves this function with information related to over 14,000 chemosensory genes and proteins. A recent addition is **ModelORDB** for molecular models of olfactory ligand–olfactory receptor interactions, closely related to **OdorDB**, which contains data on the odor molecules that have been shown to interact with the olfactory receptors. These interactions generate activity in the receptor cells which set up different activity patterns representing different odors in the olfactory glomeruli of the olfactory bulb. **OdorMapDB** contains experimental data from functional imaging of these activity patterns, which are believed to be critical for the neural basis of olfactory perception.

A final database still under construction covers the domain of brain pharmacology (**BrainPharmDB**), which expands the information for normal function contained in the other databases to neurological disorders.

The third foundation of SenseLab is integration of our own research data, by developing computational models based on state-of-the-art computational techniques. Currently, we are applying the Rall approach to analyzing the lateral inhibitory network formed by mitral and granule cells in the olfactory bulb. Studies led by Michael Hines and Michele Migliore are constructing

models which accurately represent experimental data on the differential distribution of olfactory inputs in the olfactory glomerular layer (Yu et al. 2013). We are introducing a new generation of three-dimensional models of the overlapping dendritic trees of mitral and granule cells (Migliore et al. 2013). This approach is being applied to experimental data from our own lab as well as in collaboration with other experimental labs.

SenseLab's current activities also include major contributions to neuroinformatics through participation in the Neuroscience Information Framework (NIF), the International Neuroinformatics Coordinating Facility (INCF), the Blue Brain Project (<http://bluebrain.epfl.ch/>), and the Human Brain Project (<http://humanbrainproject.eu/>). This work has included developing **DISCO**, an automated resource discovery, registration, and interoperation framework designed to facilitate data integration among Internet resources for the NIF, and **Neurolex Neuron** as an inventory of basic properties characterizing different types of neurons (see <http://neuinfo.org>).

Acknowledgments We gratefully acknowledge funding from NIH grant DC009977.

Sensory Coding, Efficiency

Franz Weber and Christian K. Machens
Molecular and Cell Biology, University of California, Berkeley, CA, USA

Definition

If a neuron's spikes are highly informative about an ensemble of stimuli, then the generated code is called efficient. The efficient coding hypothesis states that the highest levels of efficiency are reached when the ensemble of stimuli encoded by sensory neurons captures important aspects of an animal's natural environment. This notion of efficiency has been employed to explain various properties of sensory neurons including their stimulus–response functions, gain, and connectivity. Specifically, research on insect systems has shown that the stimulus–response function of many insect sensory neurons matches behaviorally relevant stimuli, while the neural gain is adjusted to the current stimulus statistics and behavioral state.

Detailed Description

To probe the properties of sensory neurons, neurophysiologists present various stimuli (e.g., gratings with different orientations for visual neurons or tones with different frequencies for auditory neurons), while recording the neural responses. Information theory provides a theoretical framework to study how much and what information a recorded neural response carries about the presented stimulus. Early influential studies focused on how single neurons in insects efficiently encode stimuli (Laughlin 1981; Bialek et al. 1991; Van Hateren 1992). In this context, a sensory neuron is defined as efficient, if its response is highly informative about behaviorally important stimuli. The efficiency of the neural code served as a first principle explaining various properties of sensory neurons including their tuning, gain, and adaptive features. More recent studies in insects have furthermore explored how changes in the behavioral state of the animal affect the efficiency of sensory processing (Maimon et al. 2010; Chiappe et al. 2010; Jung et al. 2011). Here, we will discuss concepts that have been proven important for the understanding of experimental results from invertebrate systems. Especially insect studies provided many insights on how single neurons efficiently encode stimuli. For completeness, we briefly discuss efficient coding in neural populations, even though most work on population coding has been done for mammalian systems.

Neural Codes

Most sensory neurons respond to sensory stimuli with series of action potentials, also called spike trains. These responses are usually quantified with respect to different “neural codes,” as shown in Fig. 1. The most common codes are (1) spike count or firing rate codes, in which the number of spikes within a given time window is counted; (2) spike timing codes or words, in which a spike train is binned in very short time windows, and thereby converted into a sequence of zeros (no spike) and ones (spike); and (3) time-varying rate codes, in which a spike train is filtered, e.g.,

Sensory Coding, Efficiency, Fig. 1 Neural codes. **(a)** Sensory neurons transform external stimuli into neural responses. In the example, a white-noise velocity stimulus (*left*) is presented to the identified motion-sensitive neuron H1 in the visual system of the blowfly. The velocity stimulus determines the speed $v(t)$ at which a vertical grating within the receptive field of H1 moves along the horizontal axis (see inset). Positive values represent rightward motion; negative values correspond to leftward motion. The stimulus is processed by the visual system including H1, yielding a sequence of action potentials fired by H1.

The responses of H1 elicited by the stimulus are represented on the *right*. Each row corresponds to one repetition of the stimulus, and each dot represents the time point of a single spike. **(b)** Three common schemes to quantify the neural response. The 200 ms long response by H1 indicated by the *gray box* in **(a)** is represented in three different ways: as the number of spikes within two 100 ms windows (“spike count”), as a series of zeros and ones, obtained by discretizing the spike train into 10 ms bins (“word”), and as a spike train filtered with an exponential kernel

with an exponential filter with a given decay time constant (similar to a postsynaptic potential). This type of filtered spike train interpolates between the spike count and spike timing codes. For very short time constants (1–2 ms), the code resembles a spike timing code; for very long time constants (100 s of milliseconds), the code resembles a spike count code. Especially in insects, one also finds quite often neurons with a graded voltage response, or neurons that mix such graded responses with small spikes (or spikelets) (Borst and Haag 2002). In these cases, the definition of

the neural code has to be tailored towards the properties of the specific neuron.

For all practical purposes, both the presented stimuli s and the measured responses r are often discretized and enumerated. Importantly, the mapping of a stimulus onto a neural response is usually corrupted by noise. As shown in Fig. 1a for the motion-sensitive neuron H1 in the blowfly, each presentation of the same stimulus yields a slightly different spike pattern. This variability in the neural response can be quantified by the distribution $p(r|s)$, i.e., the probability of observing response r ,

given that the stimulus was s . This distribution quantifies the noise in the transmission of the stimulus s to the responses r . If the distribution is peaked around a single stimulus value, the neuron's response is reliable; if the distribution is broad, the neuron's response is unreliable.

The noise in the neural response, here defined as trial-to-trial fluctuations elicited by the repeated representation of the same stimulus, can arise from multiple sources (Faisal et al. 2008), including the stimulus itself. External stimuli are noisy in nature. For example, the binding of olfactory molecules to taste receptors is affected by thermal noise. Vision is based on the absorption of photons which is a highly stochastic process. A further prominent source of noise stems from stochastic events in the molecular transduction machinery of sensory neurons, as, e.g., the synthesis and degradation of proteins. So-called electrical noise is generated by random openings and closings of voltage- and ligand-gated ion channels. Moreover, the biochemical communication between neurons is afflicted by noise arising from stochastic events in synaptic mechanisms (as the docking of vesicles to the membrane, the number of available vesicles, their exact locations, etc.).

The Efficiency of Neural Codes

Once the mapping between a set of sensory stimuli and the responses of a neuron has been determined, the neural efficiency can be quantified. Common measures of efficiency are the quality and precision of representation or the amount of transmitted information.

Reconstruction Quality and Precision

One particularly straightforward way of measuring the efficiency of a neural code is to try to reconstruct the original stimulus from the neural response and then simply measure the mean squared error between the original and the reconstructed stimulus. This method requires a specification of how such a reconstruction should be done. One simple method is to assume that the

original stimulus information can be read out by a linear filtering operation of the spike train. If we denote the original, time-varying stimulus by s_t , where t is a time index, and the reconstructed stimulus by $\hat{s}_t$, then a normalized measure for the efficiency of the neural code is given by the coding fraction (Gabbiani and Metzner 1999)

$$\varepsilon = 1 - \frac{\sum_{t=1}^N (s_t - \hat{s}_t)^2}{\sum_{t=1}^N s_t^2}, \quad (1)$$

where we assumed that the stimulus s_t has mean zero. This measure takes a value of zero if the reconstruction fails completely and a value of one if the reconstruction perfectly recovers the original stimulus. An important caveat is that one can only attempt to reconstruct the part of a stimulus that is represented by the neuron. Stimuli that a neuron does not respond to, e.g., because they are outside of the neuron's receptive field, or below a neuron's threshold, cannot be reconstructed (Bialek et al. 1991; Machens et al. 2001).

In a realistic experimental setting, the coding fraction ε is always smaller than one, i.e., the stimulus cannot be exactly reconstructed from the observed neural response. First, the reconstruction algorithm or estimator may be incorrect, e.g., it could be biased. Second, the transmission from the stimulus to the response is affected by noise. Given an unbiased estimator, how precisely can the stimulus be reconstructed from the response? Intuitively, the reconstruction is directly related to the shape of the likelihood function $p(r|s)$ describing the probability to observe the response r given the stimulus s . The reconstruction will be the better, the more the response distribution $p(r|s)$ varies with s , and the less $p(r|s)$ is spread out for a given value of s . For an unbiased estimator $\hat{s}$ of s , the variance of $\hat{s}$, σ_s^2 , is bounded from below by the Cramer-Rao bound

$$\sigma_s^2 \geq \frac{1}{I(s)} \quad (2)$$

where $I(s)$ denotes the Fisher information

$$I(s) = \left\langle -\frac{\partial^2 \ln P(r|s)}{\partial s^2} \right\rangle, \quad (3)$$

with $\langle \cdot \rangle$ denoting the expectation value over r for a given s . The Fisher information has become a theoretically important quantity in the study of population coding (Brunel and Nadal 1998), but has not been widely applied in the analysis of insect model systems.

Mutual Information

The reconstruction error is based on an explicit reconstruction of the original stimulus and thereby makes implicit assumptions about how the stimulus information is embedded in the neural response. A different measure that is free of these assumptions is the mutual information, which is conventionally measured in bits.

If the mapping between the stimuli s and the responses r is deterministic, then the information conveyed by the neural response is given by the entropy of the response distribution. In general, the entropy of a distribution measures how spread or peaked a distribution is. The response entropy is given by

$$H(R) = - \sum_{i=1}^N p(r_i) \log_2 p(r_i), \quad (4)$$

where each r_i , with $i = 1 \dots N$, denotes one of the possible responses. To ensure that a response r_i that is not observed, i.e., $p(r_i) = 0$, does not contribute to the entropy, it is assumed that $0 \log_2 0 = 0$. Intuitively, the response entropy increases with the number of responses encoded by the neuron. The entropy is zero, $H(R) = 0$ bits, if the neuron generates only a single response, say $r = r_0$, irrespective of the stimulus. In this case, the response is completely predictable, and the neuron thus conveys no information about the stimuli. On the other hand, the response entropy is maximal if each response symbol is observed equally often. In this case, the response is completely unpredictable, $H(R) = \log_2 N$ bits, and the neuron transmits the maximum information possible.

In real neurons, the mapping between stimuli s and responses r is usually stochastic, in which

case the neural response becomes less predictable from the stimulus. To compute the actual information conveyed, this undesirable effect needs to be measured and subtracted from the response entropy. The so-called noise entropy measures how much the response fluctuates for a given stimulus s and is evaluated as

$$H(R|s) = - \sum_{i=1}^N p(r_i|s) \log_2 p(r_i|s) \quad (5)$$

The mutual information is defined as the difference between the response entropy and the average noise entropy so that

$$I(R; S) = H(R) - \langle H(R|s) \rangle \quad (6)$$

where the angular brackets denote averaging over all stimuli s . Note that if $H(R|S) = 0$ bits, i.e., the mapping between stimulus and response is noise-free, the mutual information equals the response entropy.

The efficiency of a neural code is often quantified either directly as the mutual information, $I(R; S)$ (Borst and Theunissen 1999), or as the ratio

$$\varepsilon = \frac{I(R; S)}{H(R)} \quad (7)$$

(Rieke et al. 1997). The closer ε to one, the smaller the noise, and the more the neuron makes use of its full capacity to encode information about the stimulus.

The Efficient Coding Hypothesis

The efficient coding hypothesis states that neural systems strive to employ their full information capacity in response to natural stimuli. The natural stimuli encountered by animals are often characterized by high redundancy, meaning that parts of an image or a sound can often be predicted by knowing the rest of the image (or the sound). The task of a sensory representation is then to eliminate this redundancy. If the response entropy is maximized, the neural responses by themselves

are unpredictable, and all redundancy has been removed. If at the same time, the noise entropy is minimal, then the responses are also highly informative about the stimulus (see Eq. 6). The original formulation of the efficient coding hypothesis relied on mutual information as the key quantity to measure efficiency (Attneave 1954; Barlow 1961). However, in many instances, it has proven fruitful to assume a specific neural code, then reconstruct the original stimulus, and use the quality of this stimulus reconstruction to evaluate efficiency (Bialek et al. 1991; Rieke et al. 1997). The efficient coding hypothesis has been successfully applied both to invertebrate systems (Rieke et al. 1997; Borst and Theunissen 1999; Fairhall et al. 2001; Machens et al. 2001, 2005), mostly focusing on single neurons, and to vertebrate systems (Olshausen and Field 1996; Simoncelli and Olshausen 2001; Smith and Lewicki 2006), mostly focusing on populations of neurons. Here we focus on invertebrate systems.

Consequences and Experimental Evidence

Stimulus–Response Function of Single Neurons

In the simplest case, the stimulus s and response r are one dimensional (e.g., sound intensity or luminance of a stimulus, and firing rate or voltage response of a single neuron). The so-called input–output or stimulus–response function f maps the stimulus s onto the response r , i.e., $r = f(s)$. How should the stimulus–response function be shaped to maximize the efficiency of a sensory system?

In the limit of relatively small noise or response variability, the question can be answered precisely by resorting to probability densities and differential entropies (Laughlin 1981). The stimulus–response function should then be the cumulative probability function of the stimulus distribution $p(s)$, or

$$r = f(s) \propto \int_{-\infty}^s p(s') ds', \quad (8)$$

Sensory Coding, Efficiency, Fig. 2 Optimal stimulus–response function for a single neuron. (a) The stimuli represented by the sensory neuron follow the distribution $p(s)$. (b) The sensory system transforms the stimulus s to the neural response r carrying information about s . (c) According to the efficient coding hypothesis, the neural code is most efficient, if each response r occurs with equal probability $p(r)$. This is the case, if the stimulus–response function is proportional to the integral of the stimulus distribution $p(s)$

because in this case, all responses are equally likely. This so-called histogram equalization maximizes the response entropy and thereby the mutual information in the noise-free case (see explanations above and Fig. 2). Evidence that the input–output function of sensory neurons is indeed matched to the stimulus statistics has been provided for the large monopolar cells in the visual system of the blowfly (Laughlin 1981). The voltage of these neurons is sensitive to luminance contrasts. Measuring the contrast distribution within typical habitats of the fly revealed that the input–output function of the monopolar cells is indeed very close to the integrated stimulus distribution.

Adaptation of Stimulus–Response Functions in Single Neurons

The distribution of stimuli experienced by an animal will vary over time. Typically, the “local” distribution of stimuli encountered over a shorter time interval will differ from the “global” distribution of stimuli encountered over long stretches of time (Wark et al. 2007).

Sensory Coding, Efficiency, Fig. 3 Gain control and efficient coding. (a) Two local stimulus distributions differing in their standard deviation (a i). a ii and a iii illustrate two different coding schemes: For each local distribution, the stimulus s is represented by the same, fixed input-output function (a ii). Contrarily in a iii, the input-output function adjusts its gain to the current stimulus statistics such that each local distribution is efficiently encoded by the neural response. (b) Linear-nonlinear models are frequently applied to characterize sensory neurons. In this model, the stimulus is first convolved with a linear filter (L). The filter output is then fed through a static

nonlinearity (N) yielding a prediction of the instantaneous firing rate. The static nonlinearity can be viewed as the time-averaged stimulus-response function of the neuron. (c) The H1 neuron adjusts its gain to the statistics of the presented white-noise stimulus. In this example, two white-noise stimuli differing in their standard deviation have been presented to H1 (c i). Increasing the standard deviation of the stimulus leads to a decrease of the slope (gain) of H1's input-output function (c ii). Consequently, H1 represents both stimuli with its full response range (c iii)

A simple example is the distribution of light intensities or contrasts, which change strongly throughout the day or with the weather. For illustration, Fig. 3ai shows two different local stimulus distributions which differ in their standard deviation.

An “efficient” sensory neuron can deal with this problem in two possible ways, as illustrated in Fig. 3a. In the first solution (Fig. 3aii), the input-output function of the neuron is fixed and proportional to the global stimulus distribution. The neuron will be efficient for the global

distribution, but inefficient for any local distribution. In the second solution (Fig. 3a_{iii}), the input-output function of the neuron changes with the local stimulus distribution such that it is proportional to the integral of the current distribution. It will now be efficient for the local distribution, but inefficient for the global distribution. Given that neural responses are usually corrupted by noise, the two solutions represent trade-offs. In the first coding scheme, the local stimulus distributions are mapped onto a rather small response range (Fig. 3a_{ii}), and many of the smaller stimulus changes may be lost in the response noise. In the second coding scheme, the responses become ambiguous across different local stimulus ensembles, and the respective global information is lost (Fig. 3a_{iii}). In practice, some of the ambiguities can often be avoided if the neuron's responses can vary on different time scales. In the fly, for instance, the motion-sensitive neuron H1 changes its gain instantaneously when the variance of the presented stimulus ensemble is changed, yet the mean firing rate changes only slowly. Hence, the slow changes of the mean firing rate allow the sensory system to track slow changes in the encountered stimulus distribution (Fairhall et al. 2001).

Various studies demonstrated that sensory neurons adjust their input-output function to the local stimulus distribution (Fairhall et al. 2001; Brenner et al. 2000; Borst 2003; Borst et al. 2005; Weber et al. 2010; Rinberg and Davidowitz 2000; Geffen et al. 2009; Laughlin 1981). As an example from the fly, responses of the motion-sensitive neuron H1 to varying stimuli are shown in Fig. 3c. Here, two sets of motion stimuli that differ in the standard deviation of their velocities have been presented to the fly (Fig. 3c_i). To analyze the neuron's input-output function, a so-called linear-nonlinear (LN) model was fitted to the neural responses (see Fig. 3b). In this model, the time-varying stimulus is first convolved with a linear filter, and the filtered stimulus is then fed through a static nonlinearity, which models the neuron's input-output function. As shown in Fig. 3c_{ii}, the gain of the input-output function, as given by its slope at half maximum, is larger for the velocity profile with smaller standard deviation. Hence, the neuron is sensitive to small changes in the

stimulus. Contrarily, if the gain is small, similar stimulus values elicit similar responses. Since the gain of H1 is adjusted to the statistics of the applied velocity distribution, both stimuli are represented with H1's full response range: While the variance of both stimuli strongly differs, both response profiles in Fig. 3c_{iii} exhibit a similar variance. Thus, both stimulus distributions are efficiently represented with H1's full dynamic response range.

Maximization of Information Rates in Single Neurons

The stimulus-response functions considered above operate with spike counts or firing rates and therefore do not fully capture the inherent capacity of spike trains. The information present in a neural spike train can be measured by using the mutual information, either indirectly (e.g., by assessing the quality of a reconstruction Bialek et al. 1991; Theunissen and Miller 1991) or by binning spike trains into words and computing the mutual information between the spike timing code and the stimulus (Strong et al. 1998). In practice, these computations usually require large amounts of data since the number of stimulus and response symbols increases exponentially with the number of neurons or the length of time windows. Additionally, estimating mutual information is prone to systematic errors (or biases) if the amount of data is insufficient (Strong et al. 1998; Paninski 2003).

For single neurons, such estimates of the mutual information have usually been possible and have been computed in many systems (Rieke et al. 1997; Borst and Theunissen 1999). In turn, the information rates of different stimulus ensembles can be compared. In cockroaches, for instance, the information rates of wind-sensitive neurons change with the overall shape of the wind spectrum. If the wind spectrum shape is similar to that of an approaching predator, such as a spider, information rates are maximized (Rinberg and Davidowitz 2000). Consequently, the sensory neurons are tuned to a subspace of behaviorally relevant stimuli that convey information about predators.

In the grasshopper auditory system, information rates are maximized when the spectrum of the sounds approaches the frequencies common in grasshopper communication calls (Machens et al. 2001). Using these measures of information rates, the efficient coding hypothesis can also be inverted: Knowing the input–output function of a neuron allows one to deduce the distribution of the optimally represented stimuli. This approach has been applied to grasshopper auditory receptor neurons (Machens et al. 2005). Instead of being tuned for the average distribution of natural stimuli, the investigated neurons have been found to be optimized for behaviorally important subensembles of natural sounds, which are related to grasshopper sounds. These studies demonstrate that sensory neurons rather encode a behaviorally relevant subspace of stimuli than the distribution of all naturally occurring stimuli.

Information rates can also be used to test a system's efficiency with respect to its biophysical parameters such as the connection weights between two neurons. Using a combination of data analysis and modeling, it was shown that the coupling strength between two global motion-sensitive neurons in the blowfly, Vi and H1, is information-theoretically optimal: Changing its value, either experimentally or in simulations, led to a decrease of the information carried by the spikes (Weber et al. 2012).

Efficiency of Neural Populations

Many studies of sensory coding in insect systems have focused on single neurons. While the insect nervous system knows many instances where single neurons represent actual information bottlenecks, most information is still processed in (small) neural populations. What does the efficient coding hypothesis predict about neural populations?

In general, the efficiency of a population code can be evaluated with the same criteria as the efficiency of a single neuron. If the efficiency is measured through the mutual information, then one important aspect of an efficient code is that the response distributions of all neurons need to be statistically independent of each

other. For a population with M neurons, an efficient code therefore requires that $p(r_1, \dots, r_M) = \prod_{k=1}^M p(r_k)$. A neural population code that fulfills this condition is called a factorial code. This requirement is often difficult to fulfill. A weaker condition is that the response distributions of each neuron pair are decorrelated.

These considerations illustrate the importance of redundancy reduction as an integral part of the efficient coding hypothesis. Statistically independent or decorrelated representations will generally have a much lower degree of redundancy than the original stimulus input. The efficient coding of neural populations has been extensively investigated in various vertebrate systems (Simoncelli and Olshausen 2001; Simoncelli 2003), with only some studies on insect sensory systems (Broome et al. 2006; Geffen et al. 2009; Olsen et al. 2010). Similar to neural populations in vertebrate systems, neural populations in insects decorrelate their responses. This has been demonstrated in the olfactory system of the fly (Olsen and Wilson 2008; Olsen et al. 2010). In the antennal lobe, the second stage of olfactory processing, the so-called projection neurons receive input from the presynaptic olfactory receptor neurons (ORNs). ORNs expressing the same odorant receptor project to the same glomerulus. Different glomeruli within the antennal lobe are interconnected by inhibitory interneurons. The size of the inhibition mediated by the interneurons scales with the strength of the feedforward input from the ORNs to a glomerulus. Interestingly, the interglomerular inhibition acts at the presynaptic locus of synapses connecting the ORNs to PNs. Hence, lateral presynaptic inhibition between glomeruli mediates a gain control mechanism which accounts for variations in the strength of odorant signals (Olsen and Wilson 2008). Second, modeling of the projection neuron responses revealed that the lateral inhibition decorrelates the population response (Olsen et al. 2010).

State-Dependent Efficient Coding

Sensory neurons adjust various properties such as their gain or connectivity to match the current behaviorally important stimulus ensemble.

However, the relevance of a particular stimulus set might depend on the behavioral state of the animal. For instance, animals that are hungry show a stronger attraction to food stimuli, than animals that are full (Sengupta 2013). This type of behavioral modulation and its implications on sensory processing have been studied in fruit flies. When flies are starved, olfactory receptor neurons express higher levels of a receptor for neuropeptide F. An increased level of neuropeptide F receptors leads to a facilitation of the synapse between the olfactory receptor neurons and secondary olfactory neurons. Hence, starvation enhances the strength of synapses in the olfactory system and, thus, causes an increased sensitivity to food odors (Root et al. 2011).

Apart from hunger, an animal's locomotion state also influences the response properties of its sensory neurons, as has recently been demonstrated for flying and walking flies (Maimon et al. 2010; Chiappe et al. 2010; Jung et al. 2011). Generally, the gain of motion-sensitive lobula plate neurons in walking or flying flies is strongly increased compared to stationary animals. This gain modulation is caused by increased inputs from presynaptic elements (Maimon et al. 2010). Assuming that increased synaptic inputs correlate with an increased energy consumption, the fly's visual system seems to tightly control its resources depending on the organism's needs. During flight, visual motion stimuli might be more relevant than during a quiescent state such that the overall activity can be lowered when the fly is not flying. Moreover, since the statistics of velocities is predictably different during flight, the gain increase might be interpreted as an adjustment of the neurons' coding properties to the velocity distribution encountered during flight.

In line with this hypothesis, flying and walking induce a pronounced shift in the velocity tuning curve of lobula plate neurons. When moving, the velocity tuning is shifted towards higher speeds. This effect is likely mediated by the neuromodulator octopamine. Direct application of the octopamine agonist CDM induces a similar shift in the tuning (Jung et al. 2011). Moreover, CDM causes an increase in the baseline firing rate similar to that observed for flying or walking flies. Additionally, CDM application enhanced the

information rate (Longden and Krapp 2009, 2010). Hence, the release of a neuromodulator can adjust the coding properties of sensory neurons to the current locomotor state.

Assuming that the relevance of particular stimuli changes with the behavioral state, these results can be reconciled with the efficient coding hypothesis: Sensory neurons regulate their properties to efficiently encode what is currently behaviorally important.

Outlook

Many insect sensory neurons seem to be adjusted to the currently prevailing stimulus statistics and to the behavioral state of the animal. A large set of studies has furthermore elucidated the adaptation of sensory neurons to the ever-changing stimulus statistics of their environment. Most of these studies have been performed in "passive" animals that were not interacting with their environment. In contrast, the dependency of sensory processing on an animal's internal state or its current behavior has been less well studied. In the future, experimental work may give more insight into the biophysical mechanisms and circuits that underlie these state-driven changes in the tuning of sensory neurons. Furthermore, theoretical concepts may help to explain these changes from a normative point of view. For instance, is the state dependency of sensory neurons, such as the gain decreases in fly visual neurons during immobility, due to a necessity to save metabolic energy? Or is the state dependency fully explained by sensory adaptation to the animal's internal expectations, such as the expected distribution of motion stimuli during immobility or flight? We believe that addressing these types of questions will help us to more thoroughly understand sensory processing in animals that interact actively with their environment.

[Afferent feedback to neural oscillators](#); [Afferent input to rhythm generating networks](#); [Proprioceptive feedback to central pattern generators](#); [Sensory drive to rhythmic neuronal networks](#); [Sensory modulation of central pattern generators](#)

Definition

A central pattern generator (CPG) is an assembly of neurons (neuronal network) that produces rhythmic activity without requiring phasic input signals and often drives the motor system and rhythmic muscle movements. Sensory feedback to a CPG circuit is the return signal from the sensory system in response to this rhythmic muscle movement, which conveys a continuous measurement of the output behavior to the CPG.

Detailed Description

Individual neural networks, such as CPGs, can generate rhythmic output patterns even in the absence of any phasic input. They drive vital behaviors such as breathing, swallowing, and chewing, as well as locomotion and saccadic eye movements, and often continue to function even in isolated nervous system (i.e., in vitro) preparations (Marder and Calabrese 1996; Grillner et al. 2005; Dickinson 2006; Gordon and Whelan 2006; Isa and Sparks 2006; Kiehn 2006; Katz and Hooper 2007; Chevallier et al. 2008; Doi and Ramirez 2008; Berkowitz et al. 2010; El Manira et al. 2010; Büschges et al. 2011; Harris-Warrick 2011; Marder 2012). Given the improved accessibility for neuronal manipulations in vitro, it is

not surprising that most insights into the rhythm generating mechanisms of CPGs have been derived from this condition, and hence using preparations deprived of sensory information. In vivo, however, numerous additional influences have access to the CPG circuit from other CNS regions, circulating hormones, and sensory systems (Fig. 1). In particular for driving motor behaviors, CPGs receive constant feedback from peripheral sense organs, including proprioceptors. While CPGs may also contribute to cognitive functions (e.g., theta and gamma rhythms in the hippocampus; Grillner et al. 2005), this essay focuses on CPGs underlying motor pattern generation because the influence of sensory feedback is particularly obvious in these CPGs.

Sensory Feedback Versus Sensory Input

Sensory feedback differs from *sensory input* in that it provides the CPG with a continuous readout of the consequences of CPG activity on the resulting behavior. Typically, the sense organs providing *sensory feedback* to CPGs are proprioceptive, that is, they continuously measure the response of the muscles to the rhythmic motor output and thus show phasic activity patterns. Exteroceptive sense organs, in contrast, typically provide *sensory input*, rather than *feedback*, about changes in external conditions. They are not necessarily related to CPG activity, although in some cases they can be. To demonstrate this difference, imagine eating an almond chocolate truffle. You take a first bite from the soft chocolate layer of the truffle and your periodontal mechanoreceptors (peripheral receptors that signal information about tooth load; Bonte et al. 1993) will initially encounter little resistance and will thus either be inactive or continuously active at a low level and hence provide *sensory input*. As you encounter the almond with your second bite this changes dramatically and the periodontal mechanoreceptors now register a strong mechanical load, and they do so whenever your teeth meet the almond, in phase with the chewing pattern, providing a signal that chewing strength needs to be increased. In other words, they now provide *sensory feedback* that is directly related to the motor output. In contrast, typical proprioceptors, such as

Sensory Input to Central Pattern Generators,

Fig. 1 Schematic overview of sensory input to a CPG. For simplicity, the motor neurons are not shown separately. The CPG receives input from proprioceptive and exteroceptive pathways. This input either directly affects the CPG (local feedback) and/or is mediated via upstream control neurons (long-loop feedback). Local feedback mainly determines the magnitude and timing of CPG activity, while long-loop feedback has modulatory effects, regulates intensity and coordinates CPG activity with other motor acts. CPG activity itself can modulate incoming sensory feedback, for example, via presynaptic inhibition of the afferent pathways. *CNS* central nervous system

muscle spindles that mainly measure the stretch of muscles, provide phasic *feedback* at all times, even in the unlikely event that the manufacturer of the chocolate truffle forgot to put in the almond.

Sensory *input*, due to its (partial) independence of CPG activity, often initiates or modulates the intensity of the motor pattern on a longer time scale, adapts CPG activity to external conditions and coordinates it with other motor acts to maintain equilibrium during behavior (Grillner 2003; Dickinson 2006; Stein 2009; Blitz and Nusbaum 2011; Harris-Warrick 2011; Marder 2012). Many actions of sensory input pathways are mediated via intercalated interneurons that process many different sensory modalities and often exert modulatory influences on the CPG circuits.

Local Sensory Feedback

The role of local sensory feedback on CPG activity has been particularly well studied. CPGs are often located close to the musculoskeletal system

they control and they receive local feedback from that system (via proprioceptive pathways, or, in some cases, directly from dendrites of CPG motor neurons; Garcia-Crescioni et al. 2010). Local sensory feedback typically modifies and adapts CPG activity on a short time scale (Pearson 2004) by altering magnitude and relative timing of muscle activity. Conceptually, local sensory feedback to a CPG serves at least three main functions:

1. *Corrective input*: It can provide a corrective signal to adapt CPG patterns to deal with environmental perturbations. Corrective feedback is necessary in an unpredictable environment, for instance, to reinforce CPG activities that drive fin or body movements during swimming in rough water or to adjust wing beat in a turbulent air stream.
2. *Timing*: It can contribute to CPG activity in an *ongoing* fashion, during unperturbed motor pattern production, by providing timing cues

about the biomechanical state of the moving body part(s). During walking in cats and insects, for example, phase transitions are facilitated by sensory feedback that depends on the biomechanical state of the leg (Büschges 2005). This sensory feedback ensures that a certain phase of the movement (e.g., the swing phase) is not initiated until the appropriate biomechanical state of the leg (the posterior extreme position) has been achieved. It provides information about limb and appendage position in space and thus allows for adapting and planning of movements.

3. *Stability*: By ensuring that the timing and force output of a motor pattern is appropriate for the task at hand, local sensory feedback can also lead to a stabilization of the motor pattern. The tegula, a wing proprioceptor in locusts, for example, is excited during wing depression and hence provides feedback about the position of the wing and facilitates phase transitions (Wolf 1993). In addition, however, the tegula acts to stabilize the flight rhythm: If its nerve is stimulated with a relatively weak shock, activating only a few of the tegula's sensory neurons, the flight rhythm speeds up (Ausborn et al. 2007). If it is stimulated strongly, the pattern slows. This example nicely demonstrates that proprioceptors can have a pivotal influence on the pattern generating machinery in vivo: they work together with the CPG to ensure that the behavioral output is continuously adjusted to maintain functioning and stability of the desired pattern.

Due to these essential functions of local sensory feedback, in most systems behaviorally appropriate motor pattern generation requires both CPG activity and sensory feedback, with sensory and central mechanisms being integrated to produce a robust rhythmic activity pattern that can be rapidly adjusted to cope with unpredictable environmental disturbances.

Sensory Gating and Phase Dependent Modulation of Sensory Feedback

As is likely true for all aspects of neural signaling, the effect of sensory feedback on CPG activity is

modified by many influences. For instance, it can vary with the phase of the motor pattern at which it is given.

For example, during stick insect walking, the influence of the campaniform sensilla, which measure load of the leg, always supports phase transitions from swing to stance phase (Akay et al. 2007). Functionally, this makes sense: when load is high this means that the leg must be on the ground and stance phase should commence. Interestingly, the effect of the load receptors on the protractor and retractor muscles that move the leg forward and backward changes in sign with a switch from forward to backward walking. During forward walking, a transition from protractors to retractors is facilitated, while during backward walking transitions from retractor to protractor activity are elicited.

Another example, also from the walking system, is the phase-dependence of local sensory feedback. A perturbation that occurs during the swing phase of the leg (e.g., when the foot hits a step when climbing up a stairway) usually results in the leg being lifted to enable it to reach the next step. During the stance phase, the same stimulus causes a further descending of the leg to increase force between foot and ground, which enhances stability. Such reflex reversals have been observed in many motor systems (Skorupski and Sillar 1986; Bässler 1993; Burrows 1996), but the neuronal basis for this switch in sign is not well understood.

There are two principle possibilities for how such a reflex reversal can be achieved (Hooper 2000): (1) a differential (phase-dependent) routing of sensory feedback to different CPG neurons; and (2) a varying response by the CPG network to sensory feedback due to how the network integrates the input during different phases of the pattern. In locusts, for example, the sensory feedback from the femoral chordotonal organ, which measures the position of the femur-tibia joint during walking, is gated with the phase of the walking motor pattern, disabling feedback during certain phases of this pattern (Wolf and Burrows 1995). The underlying mechanism is a phase-dependent presynaptic inhibition of the sensory terminals and a concomitant decrease in

transmitter output. While sensory activity remains unchanged, sensory transmission to the CNS is impaired. Since presynaptic inhibition is typically strongest whenever sensory activity is high, it reduces the overall amount of sensory feedback, and, quite peculiarly, it also diminishes *expected* sensory feedback at certain phases of the CPG pattern. Presynaptic inhibition could thus be one mechanism that underlies the reafference principle, which tries to explain the fact that self-initiated motions do not interfere with the perception of constancy [proposed by von Holst and Mittelstädt (1950)]. One way to achieve this goal is via an efference copy of the motor signal (in this case the CPG output) which provides the input to a forward internal model. This model is then used to generate the predicted sensory feedback that estimates the sensory consequences of the motor command. This signal is sent to the periphery, where it (presynaptically) inhibits any proprioceptor response to the CPG-generated movement which could interfere with the execution of the motor task. Differences in the actual from the predicted sensory activity are then sent back to the CPG as an error signal to adapt the motor output. While the pathways that elicit the presynaptic inhibition are still somewhat nebulous, it has been demonstrated that proprioceptors can presynaptically inhibit the terminals of neurons from other proprioceptive sense organs (Stein and Schmitz 1999). Since proprioceptors typically show phasic activity, this could contribute to the gating of sensory feedback at specific phases of the motor pattern.

While CPG activity can affect transmitter release from sensory neurons (Wolf and Burrows 1995), so far there are no indications that CPGs can directly modulate sensory spike activity. However, CPGs may indirectly affect sensory spike activity via feedback onto modulatory neurons that not only control CPG activity, but also release neuromodulatory substances in a paracrine fashion. Neuromodulators, in turn, affect both muscle contraction and sensory activity, which makes it possible for CPGs to interfere with sensory spike activity, at least in principle (Städle et al. 2018). The activity of the anterior gastric receptor (AGR) in the stomatogastric nervous

system of crustaceans, for example, can switch from spiking to bursting, depending on the modulatory conditions present (Birmingham et al. 1999). While in spiking mode, AGR encodes both rapid and slow stimuli and thus reports cycle-by-cycle muscle movements that are driven by the CPG. In bursting mode, however, only persistent stimuli are detected and thus average levels of muscle tension are reported. This example demonstrates that the same proprioceptor can provide feedback about different qualities of the CPG output.

Context or Task-Dependent Modulation of Sensory Feedback

While phase-dependent modulation affects sensory feedback on a cycle-by-cycle basis, sensory feedback can also be subject to long-term modulation, either via the actions of neuromodulators released from neurons (paracrine, as stated in the previous paragraph) or the endocrine system (hormones) that modify the sensory response itself (Birmingham 2001) or via a modulation of the response of the CPG network to sensory input. In the stomatogastric nervous system of crustaceans, for example, changes of a few Hertz in the tonic activity of the AGR muscle proprioceptor modify the response of the gastric mill (chewing) CPG network to sensory input from mechanoreceptors in the stomach (Daur et al. 2009). Magnitude and timing of the gastric mill motor pattern elicited by the mechanoreceptive input correlate with the tonic spike activity of the muscle receptor, which means that the state of the system and its response to incoming sensory input is modified.

What Drives Rhythmic Behavior In Vivo: Sensory Feedback or CPG Activity?

Discussion regarding whether the CPG or the sensory feedback drives the actual behavior of an animal in vivo is as old as the discovery of CPG circuits. There is no universal answer, because their relative impact appears to differ from system to system. Büschges et al. (2011) draw the conclusion that, although clearly affected by sensory feedback, CPGs that drive locomotor movements in homogeneous media

such as air (flying) or water (swimming) often continue to be rhythmically active even when isolated from sensory feedback. In contrast, CPGs that drive locomotion in heterogeneous environments, such as terrestrial locomotion, typically lack rhythmic activity in isolation from local sensory feedback. This distinction, however, does not necessarily mean that sensory feedback does not shape the rhythmic movement. In locust flight, for example, the CPG can be activated in isolation and will show a stable flight pattern, but in vivo several sense organs, including the tegula, provide feedback to the CPG and dominate the motor pattern. The frequency of the rhythm, however, increases by a factor of two, which is why in this system sensory feedback is seen as a major contributor to the functional motor pattern (Ausborn et al. 2007).

While in this example there would be no flight pattern without CPG activity, theoretical approaches have proposed that sensory feedback itself could act as an oscillator if provided with the adequate properties, such as delay lines and gain (Cruse 2002). For example, a network with negative sensory feedback will produce stable oscillations if the open-loop gain is equal or larger than 1 at a frequency where the phase-shift is 180° (Nyquist criterion). It should be noted though that for nonlinear systems such as neural networks more complex stability criteria such as Lyapunov or the circle criterion, might be necessary. Networks with positive feedback, on the other hand, need a high-pass filter or related mechanism that reduces the positive feedback to create stable oscillations (Bässler 1986). In both cases, the oscillations would be driven entirely by sensory feedback and might not even require a central oscillatory network. In such a case, the system would be called a chain reflex (because a system that *must* be driven by sensory input is defined as a reflex). In fact, a chain reflex may not be distinguishable from a CPG in vivo (Bässler 1986). If we consider a relaxation oscillator as a pattern generating circuit (e.g., a half-center circuit with reciprocal inhibition, as is found in many systems), the frequency of the oscillations would depend on the endogenous excitation of the loop

and its internal characteristics (gain and time constant of the fatigue of the positive feedback). Sensory feedback could affect oscillation frequency either by affecting the intrinsic characteristics or by modifying the excitation state of the network. Even in the easiest situation of a simple addition of excitation to the oscillator neurons by the sensory feedback, the timing cues for switching between oscillation states would depend on the sensory feedback, and the CPG would only be responsible for managing the actual switch between phases. If the endogenous excitation in such a relaxation oscillator network would fall below the threshold for oscillations, the sensory feedback could substitute for the lack of endogenous excitation and elicit oscillations. Per definition, this would then be a chain reflex.

Even if the CPG consists of a negative feedback loop (such as serial inhibition in a network with an odd number of neurons), sensory feedback would drive the frequency of the oscillation. In such a system, the CPG oscillation frequency depends on the amplitude and phase-frequency oscillations of the open-loop system. If sensory feedback is added to the system, the eigenfrequency stays the same and the sensory input will be damped and superimposed on the inherent (CPG) oscillations (Cruse 2009). The resulting frequency will thus be a superposition of central and sensory oscillations. Sensory feedback, however, will entrain the central oscillations within a given range. Thus, the CPG represents a band-pass filter for the sensory oscillation. In the passband, the timing cues of the oscillations are determined by the sensory feedback. In summary, determining whether the CPG or sensory feedback dominates the behavior of the oscillatory system in vivo, although of pivotal importance for understanding the dynamics of motor systems, continues to challenge studies of CPG function.

Long Loop Sensory Feedback and Long Lasting Effects of Sensory Feedback

While one role of sensory feedback is to allow the CPG to deal with environmental perturbations (corrective input), certain motor pattern characteristics such as phase relationships must be

maintained to guarantee functional and behavioral homeostasis. Sensory changes from one part of the pattern, for example, might require compensatory changes in other parts. Thus, the effects of local sensory feedback might have widespread and possibly long-lasting effects.

Sensory pathways also affect CPGs indirectly, by influencing the neurons that control the CPGs. In the locomotor systems of cats and lampreys, for example, supraspinal networks in the brainstem receive sensory input from many modalities, including proprioceptive feedback (Rossignol et al. 2006). While in general these upstream neurons are involved in pattern initiation, modulation, and selection, the uniquely identifiable reticulospinal Mauthner and Müller cells in lampreys display movement related activities that appear to be elicited by ascending feedback from the CPGs (Antri et al. 2009; Buchanan 2011). This is similar to modulatory projection neurons that control the CPGs in the stomatogastric nervous system (Blitz and Nusbaum 2012). Here, ascending feedback from CPG neurons impose a rhythmic activity pattern onto these modulatory neurons. In both cases, neurons outside of the CPG have access to the timing of the CPG and they are affected by sensory input. In the stomatogastric nervous system, phasic sensory feedback affects the very set of projection neurons that shows CPG timing (Hedrich et al. 2009), which allows for a long-loop sensory control of CPG activity. In lobsters, for example, the phasing of CPG activity can reverse activity if the proprioceptive AGR neuron exceeds a certain threshold (Combes et al. 1999), due to the bistable intrinsic properties of modulatory projection neurons that process sensory feedback from AGR.

Open-Loop Versus Closed-Loop Sensorimotor Interactions

Even if sensory feedback only exerts short-acting effects, compensatory changes in the motor pattern may occur and induce global, long-lasting changes in the CPG pattern, because the activity changes of the neurons targeted by sensory feedback may induce changes in a chain of followers. Yet, relatively little is known about such holistic

sensorimotor interactions. This is mostly due to the fact that while sensory feedback has been studied in many motor circuits, this was typically done in open-loop conditions, that is, with emphasis on how sensory signals alter motor output (rather than interact with it), or on information flow toward that output. The dynamical components determined by the interaction of motor and sensory activities, however, can create emergent properties that govern the functional characteristics of the system. While already a standard for investigating movement or behavior in general (e.g., fly and bee flight: Dickinson 2005; Fry et al. 2008; Mronz and Lehmann 2008; Sareen et al. 2011; Srinivasan 2011; monkey motor control and vision: Nicolelis 2003), the idiosyncratic dynamics created by the sensorimotor interaction have only rarely been elucidated at the level of the nervous system.

One reason for the discrepancy between closed-loop behavioral and open-loop nervous system studies is the unfortunate fact that sensory structures, and thus also sensory feedback, are typically not available in experiments performed in isolation from the body. The functional and circuit properties as well as the cellular characteristics of CPG networks, however, are only known in great detail because of their accessibility in isolated preparations. In contrast, in systems with well-characterized behavior and sensory structures, the underlying neural network is usually not well-described. One way to circumvent this problem is to provide artificial sensory feedback that depends on the motor output, in real-time, to the isolated CPG circuit. Thus far, in the few instances in which such closed-loop experiments have been performed (Bässler and Nothof 1994; Ausborn et al. 2007; Smarandache et al. 2008; Ausborn et al. 2009), it is clear that sensorimotor interactions pivotally shape the motor output. Given the fact that sensory feedback also affects the upstream neural structures that control the motor circuits, it seems reasonable to assume that sensory feedback in closed-loop conditions will have an impact on the motor pattern that goes beyond simple influences on timing and magnitude. Rather, emergent properties of sensorimotor interactions are to be expected.

Indirect and Long-Term Influences of Sensory Feedback

While the immediate influences on timing and magnitude of sensory feedback are well-studied, sensory feedback also has long-term influences on CPG activity.

1. Development of vital rhythmic activities: It is still unclear whether sensory feedback is needed during early nervous system development (Suster and Bate 2002). A lack of feedback, however, leads to dysplasia or coordination problems later in life.
2. Stability and robustness of the motor pattern during the life span of the animal. While motor circuits must be flexible in order to respond to changes in the environment or the body conditions, they must also generate stable patterns and be robust against perturbations. Emergent properties of sensorimotor interactions may well supply the basis for stability and robustness and may even help to select the adequate motor pattern, biasing the system towards specific patterns. In particular when environmental or neuromodulatory conditions change, robustness must be present. Failures of this control may be fatal (e.g., sudden infant death syndrome).
3. Recovery from injury. Continuous CPG activity requires CNS input and removal of this input causes a failure of the motor pattern. While there is some evidence that continuous entrainment of the motor patterns via sensory feedback supports recovery (e.g., after spinal cord injury; Rossignol and Frigon 2011; Mehrholz et al. 2012), it is far from clear what mechanisms drive recovery. Emergent properties during sensorimotor interactions might support recovery, in particular if neuromodulatory neurons (long-loop sensory influences) are involved. Sensory feedback could in this case replace the missing endogenous excitation of the CPG network.

In summary, while CPGs generate rhythmic activity patterns that have similarities to the behavioral patterns, sensory feedback pivotally shapes the CPG output. While the short-term and

direct actions of sensory feedback on CPG activity are well-described, their long-term actions and sensorimotor interactions in closed-loop conditions are a focus of current studies.

3D Shape Perception, Models of

Benjamin Kunsberg¹ and Steven W. Zucker²

¹Division of Applied Mathematics, Brown University, Providence, RI, USA

²Department of Computer Science, Yale University, New Haven, CT, USA

Definition

A 3D shape percept is the psychophysical response induced from a visual stimulus. The

percept is the result of (partially) unknown neural processes within the visual system. Psychophysical tests of performance have mainly involved humans, and most relevant neurophysiological research (to date) has been performed on primates. The challenges are that (i) many different visual areas can be involved in producing a shape percept; and (ii) a single image rarely constrains the potential shape possibilities to a unique percept. Therefore, the visual system (and our computational models) must exploit assumptions to restrict the range and type of solutions. Since most models seek to return a single and, to some extent, veridical 3D shape percept, understanding both the assumptions needed and the mechanisms of computation are key components of research.

Detailed Description

An Ill-posed Inverse Problem

When a 3D object must be recovered from a single image of the object, the inverse problem is ill-posed. This is because the image (e.g., photograph or retinal image) is a result of a projection of the 3D world onto the camera sensor or retina. A projection (see Figure 1) identifies all the points along a single ray with a single image point. Once this projection has occurred, the information about the depth of the true 3D point has been lost. Thus, imaging of different shapes can result

3D Shape Perception, Models of, Fig. 1 Ill-posedness, or the ambiguity inherent in recovering 3D shape from a projection. Each of the three cartoon surfaces sketched in blue can be described (in a low resolution manner) by a collection of three points in depth (yellow, red, green) along perspective rays emanating from the camera. Each point can be arbitrarily far along the ray; there is only hope to recover their depth if assumptions are made about how the image (e.g., the color of the points) is related to the surface depth

in precisely the same image (Belhumeur and Kriegman 1998).

In order to combat this ill-posedness, our brain (and our algorithms) must use assumptions regarding the original surface. These assumptions codify regularities about the surface and the environment in which it was imaged. For example, in shape from shading (Horn and Brooks 1989), a common assumption is that the object is smooth and the image intensity value corresponds to the interaction between the object's normal field and the light sources. In shape from texture (Witkin 1981), the image may be understood to result from foreshortened texture elements. In both of these cases, these assumptions (and additional ones) may allow for surface shape to be recovered. However, there is a tension between the severity of the assumptions—e.g., Lambertian reflectance—and relevance in the natural world. This brings us to the second major difficulty:

The Diversity of Image Cues

3D percepts derive from an incredible diversity of image cues. Images of the same 3D shape can differ greatly, depending on the type of material (i.e., its bidirectional reflectance distribution function, or BRDF), cue, or environment. In Figure 2, we illustrate this point by showing a shape with three different cues: diffuse shading, specular shading, and texture. In each of these cases, the values of image intensity from corresponding

surface points may differ drastically. Thus, the relationship between individual intensities and surface shape is heavily dependent on the type of cue, which is unknown a priori. Even more remarkable is that the visual system achieves a degree of *shape constancy*, meaning that the same shape can be recognized when seen from novel views, with novel materials, and in novel environments. Although our abilities are impressive, we emphasize that constancy is neither perfect nor quantitatively invariant across individuals, although informally it might seem so.

Given only an image, how does the human visual system efficiently understand the surface shape while also interpreting the cue? What are the neural representations of 3D objects? Does the visual system “memorize” an object as a collection of 2D images collected from different views or does it achieve some type of 3D representation? To what extent does the visual system achieve shape constancy, and how does this vary with viewpoint, lighting, and material? These are some of the questions involved in understanding 3D shape perception.

Research into 3D Perception

The literature is filled with many computational studies, models, and algorithms for reconstructing a 3D shape from an input image(s). Perhaps the earliest one, which set the stage for much of the modern research, is Ernst Mach's work in the

3D Shape Perception, Models of, Fig. 2 An example of three different images of the same object from same viewpoint but rendered from different image cues. Left: An object under diffuse shading. Center: A specular shaded

object. Right: A textured and shaded object. A sufficient model of 3D shape perception should be able to handle these different cues. (Figure courtesy Shivam Nadimpalli)

middle of the nineteenth century (see the translations in Mach (1965)), which formulated the problem as a differential equation, discussed the difficulty in solving it, and assessed the phenomenology of human performance.

Nevertheless, although the problem is inherently interdisciplinary, the perception of 3D shape has been investigated (roughly independently) within several different fields, including neuroscience, psychology/psychophysics, and computer vision, and the interactions between them have ranged from weak to occasionally intensive. Psychologists take a large-scale, almost black-box approach, and study how the full visual system could work as a whole; they seek to understand the relationship between input and output representations. Their interest (and the models) is largely phenomenological; they wish to understand performance and behavioral limits and answer the question: “what do we see?”

From the perspective of neuroscientists, vision is a problem whose solution requires a deep understanding of the individual neurons, how they are connected, and what is their preferred stimulus. They investigate the local circuitry and the role of different cortical areas. Neuroscientists look inside the black-box to study the mechanisms involved. They wish to understand: “how do we see?”

Computer scientists seek algorithms for useful tasks such as visual categorization and scene understanding. Some motivation is application driven (e.g., biomedical applications); some is algorithm driven (e.g., regularization), and some is inspired by either human capability (e.g., autonomous vehicles) or neurophysiological insight. Thus, like neuroscientists, some computer scientists are interested in the architecture behind the computations. They build applications for constrained domains (e.g., shape-from-shading and shape-from-motion) and wish to answer: “how can machines see?”

Clearly the different approaches are interrelated, and the cross pollination is important. We will review certain key points in this complex research program in roughly chronological order, starting with models that were under the purview of psychology. More recently, innovations in

cellular recording have allowed researchers to gather electrophysiological data to support certain theories. We will conclude with descriptions of related computer vision algorithms. These different threads through our dialogue remain tangled, to some extent, which highlights the interdisciplinary nature of the problem.

Psychology and Psychophysics

In psychology, there have been numerous studies considering the priors and models the brain uses in the perception of 3D objects. This is often done in two ways: with computational models simulating the process and psychophysical experiments.

Psychological research consists, for starters, of psychophysical experiments. A visual stimulus is shown to a subject, after which the subject performs a task related to their perception of the stimulus. The difficulty is finding tasks that isolate and inform a single property; this allows meaningful conclusions to be drawn from the task performance. Often psychophysical experiments are used to advocate for or against the computational models that are much too general to test via intracellular recordings. Below, we describe several major themes running through modern investigations into 3D shape perception.

Intuitively, perhaps the easiest route from 2D to 3D is with multiple images in space (namely, stereo) or multiple images in time (structure from motion). Both of these were actively pursued; see Howard and Rogers (1995) and Kolars (2013), respectively, for reviews; we shall only occasionally discuss these here. Rather, the concentration will be on shape inferences from a single, time-invariant image.

Invariants and Affordance

Gibson’s “ecological” approach to explaining 3D shape constancy was through an emphasis on “invariants”. Gibson believed that 3D shapes were perceived veridically (contrary to some of his contemporaries), and he posited that this was due to physical invariants in the 2D image that directly corresponded to the true 3D shape (Gibson 1979). For example, Gibson was the first to test how textures lead to perception of surface slant (Gibson and Cornsweet 1952). He

proposed that perception was based on the spatial gradients in the textures and the necessary inverse to shear these spatial gradients back into an isotropic texture. This was an early example of an inverse optics approach. It was built on foundations established by the Gestalt psychologists (Metzger 1936) and it stimulated much work that came later.

Unlike computational theorists, Gibson believed that the visual system “directly” perceived these invariants, and by computing only on them, was able to achieve some degree of shape constancy. He may have been the first to attempt computationally to “extract informative variables from raw light” (Warren 2012), but see Ullman (1980) for a critique.

The Gibson school also addressed motion (Cutting 1986), but it was in this context that more computational research started to accelerate (Ullman 1979). This push-and-pull between phenomenological observations and computational concreteness continues to the current period and underlines the interdisciplinary nature of the problem.

Computational Modules

Marr synthesized much work on 3D perception (Marr 1982), and “made it clear that a computational model is critical” (Pizlo 2008). He attempted to understand the computational tasks needed to turn early information into surface orientations and then a 3D model.

His ideas elucidated a computational framework for vision that focused on “taking slant into account.” Following Horn (discussed later), he believed that 3D shape perception is based on the local 3D surface orientation. Following work in software engineering (Brooks Jr 1995), he sought to split the 3D vision problem up into a sequence of modular problems, each with increasingly symbolic representations. The symbolic emphasis built on influences from AI and cognitive science (Pylyshyn 1986), integrated with research in image processing (Rosenfeld and Kak 1982). The first stage was extracting important lines and edges from the image and using these to construct a “primal sketch.” (This followed directly in the lines of Gestalt

psychology (Koffka 1955) and perceptual organization.) These edges and lines could then be interpreted as depth or orientation cues, called a “2.5D sketch,” in a viewer-centered frame. The 2.5D sketch could then be attributed to surface primitives and eventually be converted into an object-centric 3D volumetric structure based on generalized cylinders (discussed below). This viewpoint was very influential and led to many investigations attempting to perform one of these steps; see Fig. 3 boxes 1B and 2B.

Marr and many contemporaries believed that the local surface orientation was an important surface feature that could be observed from the image and then integrated into a 3D shape representation. Several investigators, e.g., (Stevens 1983; Witkin 1980; Koenderink and Van Doorn 1980a; Koenderink et al. 1992; Koenderink 1984), expanded on this idea. Koenderink et al. introduced the gauge-figure experiments for detecting local perceived surface orientation (Koenderink et al. 1992). Marr’s ideas (insistence on slant and depth fields) eventually came into conflict with the requirement for 3D primitives. Later ideas by Biederman, expanded on below, rather considered 2D projected features of a set of volumetric primitives.

Although compelling, many of Marr’s ideas on object recognition were eventually superseded. Marr assumed that the goal of the visual system was to acquire a general purpose, Euclidean, representation of the world. But psychophysics experiments began to show that the visual system rarely achieves such a veridical solution, and his computational ideas were unable to handle real-world noise. However, his convincing prose and beautiful demonstrations shaped the field for a decade or more.

Volumetric Primitives

It is clear that neurons in the visual system form a hierarchy (Hubel 1988). Hierarchical systems are efficient as they start with simple parts and construct more complex “objects” from the simple parts, and computation is limited as the representation becomes more abstract. Thus it is natural to ask the question: “What are the primitives (beginning elements) the brain uses to understand

3D Shape Perception, Models of, Fig. 3 A diagram of different theories for the visual system. Across the columns, we change the level of abstraction. For example, the first column considers models based directly on image pixels and appropriate for computations in the early visual system. The third column consists of computations on higher areas of the visual system which are conjectured to

involve 3D volumetric understanding. Across the rows, we have placed theories according to increasing robustness to changes in “world properties.” The first row consists of structures that may be brittle when, e.g., illumination direction is changed, whereas the third row contains structures that may be invariant

and categorize 3D objects?” There have been many theories that attempt to model complex 3D objects through compositions of primitive 3D objects. However, the primitives need to be chosen carefully as they need to have explanatory power while also being recognizable from their 2D retinal images. (This line of research is a generalization of medial axis representations for 2D shapes (Siddiqi and Pizer 2008). Importantly, the medial axis shares much in common with the (projected) main axis for generalized cylinders.) A powerful choice for these primitives is simple volumetric 3D shapes with small numbers of parameters. It is necessary that they are distinguishable from image features, regardless of the viewpoint. (See Figure 3, 3rd column.) Importantly, such models underline the transition from

local features, such as edges or surface curvatures, to global descriptors. Their psychophysical origins may date from the Johansson biological motion demonstrations (Johansson 1973) and the 3D rotation experiments by Shepard Metzler (1971), but had their direct origins in a computer vision approach, namely Binford’s generalized cones (Binford 1971). This influential model showed that combinations of generalized cones could model a large variety of objects. It continued with Biederman’s (1987) “recognition-by-components” theory, in which 3D perception was modeled via combinations of simple geometric components called *geons*. For example, a flashlight can be represented as a cylinder attached to a flared cone and a small rectangular solid (the switch). These geons were chosen by

informally considering nonaccidental properties and still have an important legacy in visual psychophysics and design (Norman 2002). However, Biederman's approach needs salient contours and established figure/ground organization which, at the time, were not directly computable from an image. Later, Dickinson et al. (1992), among others, expanded on these ideas by building a working algorithm operating on simple images without figure/ground organization and returning correct interpretations and decompositions of the image parts into the volumetric 3D primitives. Although there was progress, "real images do not allow unambiguous recognition of parts" (Pizlo 2008). This research direction eventually foundered because of this pragmatic computational issue and, as of 10 years ago, "today's systems focus on 2D configurations of local image-based features rather than on 3D configurations of shape-based volumetric features" (Pizlo 2008). (We shall discuss more recent computational approaches shortly.)

The geon concept remains a driving force conceptually and an anchor for thinking about shape. It also spawned a fascinating debate about invariances over viewpoint and lighting, which played out directly against appearance models.

Appearance Models

By the early 1990s, practical shortcomings in the above theories were becoming pressing, so researchers began to reexamine the assumption that perceptual representations were, in fact, "3D." Perhaps the visual system simply "memorizes" a collection of 2D views of an object? Could this still explain shape constancy?

Influential papers by Ullman (1989) and Poggio and Edelman (1990) suggested alternate theories, called appearance models (see Fig. 3), for object recognition. In Ullman (1989), it was suggested that object recognition could be obtained from a novel view by considering it as a linear combination of images learned in previous views. In Poggio and Edelman (1990), a network of radial basis functions was trained to map images from one viewpoint into a "standard" viewpoint. This allowed for comparison and thus

object recognition. Both of the above methods hypothesized that 3D shape perception was nothing more a collection of 2D images with perhaps an alignment or extrapolation mechanism, an idea favored in insect vision (Collett 2010) and deployed today in face recognition and related problems.

Importantly, the appearance model's collections of views were associated with learning, and geons were interpreted as fixed. This leads to testable hypotheses (Bülthoff and Edelman 1992), which favored these new theories against those that used 3D model alignment. However, this association of 2D views with learning versus fixed 3D representations had other issues regarding invariance; we shall return to these in the last section. Nevertheless, algorithms for object recognition have largely focused on extracting and recognizing 2D features from the image. This is more convenient computationally, although recent psychophysical experiments by Pizlo, Todd, and others (Pizlo 2008; Fleming et al. 2011; Farley Norman et al. 1995) show that 3D structure is still reliably inferred from ill-posed 2D images. In this way, the computer vision community and the 3D perception community have split: while the computer vision scientists mainly use 2D image features for their purposes, many vision scientists still believe the brain computes 3D structures.

Bayesian Models

Computational difficulties with the modular and the appearance approaches were brought to the forefront by phenomenological approaches that considered the interaction between lighting, depth, surfaces, and viewer position simultaneously. Convincing demonstrations (Yuille and Kersten 2006) forced a retreat from Lambertian models and forced the field to confront the difficulties of natural images. Popular Bayesian methods introduced a massive search for priors, providing a mechanism for relating structure in the world to that manner in which we recover it. Such approaches suggest that we are wired to see what we expect to see (Knill and Richards 1996), which brings us to neuroscience.

Neuroscience and Neurobiology

The fundamental goal for neuroscientists studying 3D perception is to understand the neural circuitry and mechanisms that allow the visual system to perceive the 3D world with such accuracy and flexibility. To this end, they have studied neural representations, often through intracellular recordings in V4 (the fourth visual area), inferotemporal cortex, and other visual areas. Simply explained, “awake and behaving” primates are trained to fixate while viewing images on a computer monitor. Electrodes (and now imaging) report the activity in targeted visual areas. By carefully choosing and modifying the type of stimulus, they attempt to capture a cell’s preferred stimulus; such preferred stimuli are then used as evidence for certain perceptual theories.

We already mentioned the hierarchy of Hubel and Wiesel, but their work also provided the usual starting point for theories of image representation in the visual system. In (Hubel 1988), they argued there are two types of cells in V1: the first type are simple cells tuned to sinusoidal gratings and often modeled with Gabor filters. The second type, complex cells, has a larger retinotopic tuning that “pool” over the simple cells. The complex cells become spatially invariant, to a small extent, whereas the simple cells have spatial selectivity. These results inform the initial theories for 2D representations of images in the brain. The logical next step would be to search for cells tuned to a representation for 3D surfaces. Much work has been expended to understand stereo (Cormack

et al. 2017) and motion (Britten et al. 1992) in this regard.

The debate above, between appearance models and volumetric models, was also addressed physiologically. We highlight two notable studies; one from each side. The first is Logothetis et al. (1995), where inferotemporal (IT) neurons were found in monkeys that responded selectively to specific views of unfamiliar objects. The discharge rate of these neurons were bell-shaped functions of orientation centered around their preferred view. The finding was interpreted as supporting theories (such as the appearance models described above) where a 3D object recognition system was encoded via a population of neurons tuned to different views.

The second impressive study investigating the preferred stimulus of IT neurons is Yamane et al. (2008). See Figure 4. They found results that agreed more with the volumetric primitive approach. By carefully modulating a 3D rendered shaded stimulus through a genetic algorithm, they found preferred 3D stimuli for a collection of IT neurons. Remarkably, these IT neurons responded invariably even when the light source, x-y position, and object depth were changed. The IT neurons stopped responding when the shading was removed, implying that the 2D boundary stimulus did not suffice. This suggested that these neurons were tuned to the 3D shape cues expressed via shading or disparity, rather than 2D features in the retinal projection. Importantly, the response was nonlinear with respect to the 3D primitives that

3D Shape Perception, Models of, Fig. 4 Figures from (Yamane et al. 2008). In this work, Yamane et al. identified preferred stimulus from IT (inferotemporal) neurons in macaque monkeys. The preferred stimuli were found via a genetic algorithm and shown to have similar 3D structure. The redness of the image corresponds to the neuron’s preference. Left: An example of modifying a 2D image of a

3D stimulus in a part-based fashion to search for the neuron’s preferred stimuli. Center: The preferred stimuli found for one IT neuron. Note the commonality in the 3D structure across the stimuli. Right: A light source invariance was found for several stimuli. Changing the direction of the light source (and thus the image of the 3D object) did not change the response of the neuron

composed the stimuli; this means the neurons required several 3D features in specific relative positions and orientations in order to respond positively.

An early and more complete review of neurophysiological studies on visual recognition can be found in Logothetis and Sheinberg (1996). Closer to this review are neurophysiological studies of shape and the inferotemporal area of visual cortex (Tanaka 1996). We now summarize other research in the field of computer vision that is relevant to 3D shape perception.

Computer Vision

In computer vision, there are often two competing goals. The first is application driven and involves specialized techniques for targeted areas, such as fMRI or facial image analysis. Studies of this type typically have little, or no, connection to biological information processing. The second goal is to build algorithms that are “as good as a human” in computing the 3D shape from images, although not necessarily requiring that models are biologically plausible (computable under the brain’s constraints and according to properties observed in the experiments described above). Rather, in computer vision, the incentive is higher performance on benchmark datasets collected, e.g., in support of autonomous driving. “Models” may then be only broadly interpreted to mean algorithms that could be weakly inspired by known properties of the visual system’s mechanisms. Such inspired properties include ideas like hierarchical units, spatial pooling, multiscale representations, and Bayesian priors. Below we describe efforts of this nature; we will first describe some earlier image reconstruction approaches and then discuss multiview approaches.

Differential Equation Approaches

The first major effort in computing shape from a single image was the work of Horn (1970) in the 1970s. Like Mach earlier, he focused on understanding the inverse process for Lambertian shaded images. His reflectance map approach translated the problem into a partial differential equation (PDE) which, like Mach, he solved via the method of characteristic strips.

The logic behind the PDE approach is that, for Lambertian shading, the brightness at a point relates to the projection of the surface normal onto the light source position. Therefore, a change in brightness (derivative with respect to the image) relates to a change in normal (a type of curvature).

Central to the PDE approach are boundary conditions; for example, a curve along which the solution is known. Although there is substantial psychophysical evidence that boundaries matter substantially (Ramachandran 1988), uniqueness and stability remain elusive in general (Deift and Sylvester 1981).

The PDE work led to other classical approaches (Horn 1986; Horn and Brooks 1989), often posing the problem as one of cost function minimization (regularization (Poggio et al. 1985)) rather than a propagation: one defines various penalty terms based on the surfaces desired and cues expected. These penalty terms may correspond to surface smoothness, constant albedo, boundary constraints, etc. The defining characteristics of the model are then the choice and justification of these penalty terms. Many penalty terms have been suggested for a vast array of image cues, including shaded (Horn and Brooks 1989; Barron and Malik 2012; Zhang et al. 1999), textured (Witkin 1981), symmetrical (Pizlo 2008), and polyhedral surfaces (Pizlo 2008). One of the benefits of regularization is that it sidesteps the issue of solution uniqueness and only attempts to find some local minimum. Related to the cost function approach is the Bayesian approach.

Bayesian Approach

The classical regularization approaches were mainly deterministic and did not explicitly take into account noise. Bayesian approaches that more explicitly built noise into the models gained traction in the 1990s. The assumptions about the natural world from the deterministic approaches can more generally be described as Bayesian “priors.” However, there is a philosophical tradeoff between the “firm” computational theory of constraints, e.g., as described by Marr, and the statistical machinery of the Bayesian framework. With the deterministic approaches, there is a firm

basis on which the intermediate stages of the model can be interpreted. This understanding is less viable with Bayesian approaches. Second, a priori constraints in deterministic problems restrict the domain of the solution (Poggio et al. 1985); “they are not used like priors to refine the solution” (Pizlo et al. 2014).

One example, the framework of Bayesian graphical models, has been successful in recovering 3D shape from an image. In the Markov Random Field framework (Geman and Graffigne 1986), the goal may be to solve for the latent variables of a graph network which together define the depth function of the unknown surface (Saxena et al. 2005). The known variables are local image properties, and the potentials involve similar constraints to the penalty terms used above.

Deep Learning

Recently, deep learning has been applied to reconstructing 3D shape from a single image (Liu et al. 2015; Eigen et al. 2014). The results involve training convolutional neural networks (CNNs) on large public datasets. Although very promising for applications, the deep learning results on shape-from-shading do not inform or validate theories of perception. Understanding the visual system’s abilities is only loosely tied to training these deep networks, because of the need for labeled training examples. However, some have argued that there are relationships between deep networks and object recognition (Yamins and Dicarlo 2016) and others have been inspired by research into human perception, such as Marr’s 2.5D sketch theory (Marr 1982), in building deep architectures (Wu et al. 2017).

Multi-image Reconstruction

Although we only mentioned stereo at the beginning of this review, it has achieved a substantial level of success in computer vision. 3D reconstruction becomes easier if several images of the same object are available, either from different positions or under different controlled lightings. In this case, the problem is different philosophically as it becomes well-posed or even over-posed. The issue becomes one of using and

combining the correct matching information across the abundant data. The most common example is binocular (stereo) vision, where there is a pair of calibrated images as input. In this case, the use of epipolar geometry will define the depth map provided a correspondence matching problem can be solved (Longuet-Higgins 1981; Scharstein and Szeliski 2002; Li and Zucker 2010).

Other work in multi-image reconstruction is structure from motion (to compute camera parameters) (Tomasi and Kanade 1992), optical flow (Barron et al. 1994), and multi-view stereo (Seitz et al. 2006).

Recent Integrative Shape Perception Theories

Several threads can be pulled from the studies reviewed above, and their historical evolution. Perhaps the main tendency in shape inference is to isolate one aspect of the problem and then develop a rich theory of it. This could be the dependence on a single – and simple – lighting model (e.g., Lambertian); the assumption of known parameters (e.g., light source position); or assumed factors (material properties or albedo). The other extreme is to work with “natural” images, e.g., office scenes, and exploit expectations about their overall properties (e.g., tables are flat). Both threads have advantages, but both suffer shortcomings. There are two possibilities for progress: enlarge the threads to integrate different requirements into theories. We now mention an example of each of these.

Recent work has attempted to enlarge these threads to include drastically different rendering models and shape properties. Building on shading isophotes (Koenderink and Van Doorn 1980b) and flows (Breton and Zucker 1996), Fleming et al. (2011, 2004) have investigated the use of orientation fields as the underlying framework for 3D perception in specular shading. Vergne et al. expanded on that work by showing how deformations of the orientation field can modify 3D image perceptions (Vergne et al. 2012). Such approaches integrate information about photonics (isophotes), visual cortex (flows), and non-standard rendering models (specularity). Regarding different properties, Pizlo et al. (2014) and colleagues study the

3D Shape Perception, Models of, Fig. 5 In Kunsberg and Zucker (2018), it is proposed to describe important surface features via the Morse-Smale complex of the image. Parts of this structure are robust with respect to illumination conditions and other rendering changes. Here, we show the first eight preferred stimuli from Fig. 4 and how the Morse-Smale complex of the image gives a consistent segmentation of those surfaces into two

“lobes.” The red and green points represent maxima and saddle points of the image, while the blue curves represent separatrices. Note a common separatrix (blue curve) is always aligned in the “southeast” direction. This may explain: (i) the similarity between the preferred stimuli and (ii) the light source invariance (Kunsberg and Zucker 2018) found for those stimuli

implications of hard symmetry constraints. By carefully defining “3D shape” to be fundamentally based on symmetry, they have explained a body of conflicting research on shape constancy (Pizlo 2008; Dickinson and Pizlo 2013).

Two other significant directions are derived from mathematical and psychophysical consideration. First, shape inferences are global, so local (e.g., differential geometric) techniques are questionable. Second, psychophysically it has been determined that shape percepts are qualitatively but not quantitatively identical; see, e.g., shape constancy psychophysical results in Mooney and Anderson (2014), Khang et al. (2007), Faisman and Langer (2013), Sun and Schofield (2012), and Koenderink et al. (2015). In light of these points, Kunsberg and Zucker (2018) have proposed using topological image features of the orientation flow (described by the Morse-Smale complex) to extract a relevant surface segmentation into “bumps” and “valleys.” Their motivation is that a qualitative representation more accurately models the lighting invariance that is commonly

part of our subjective experience. This is also seen explicitly in the electrophysiological results from the Connor lab (Yamane et al. 2008). Inspired by image invariants from Gibson’s approach and volumetric primitives from Biederman’s theories, Kunsberg sought a 3D representation based on 2D image curves with an invariance to rendering functions. By focusing on the invariant features of the image, the visual system may be able to extract weak (nonmetric) yet intuitive 3D relationships without needing to identify the precise cue. See Figure 5.

Summary

Although shape inferences have been studied experimentally, formally and computationally for more than a century, many conundrums remain. How does the visual system infer shape from translucent objects (Kim et al. 2014)? How can it compute shape from shading “on a cloudy day” (Langer and Zucker 1994)? What about metallic and specular objects (Fleming et al. 2004; Todd and Norman 2018; Adato et al.

2010)? Are there multiple “modes” that it can access for different cases (Sun and Schofield 2012)? Or perhaps the goal of the visual system is not to perceive veridically (Koenderink 2011; Hoffman et al. 2015).

Fortunately, there is an active research community in 3D perception attempting to understand the above questions and find a unifying framework for shape constancy. Understanding 3D perception would not only be a scientific triumph but would also lead to breakthroughs in many computer vision and industrial applications. It would contribute to artistic understanding and rendering applications such as computer graphics. Most importantly, we would understand one of the most intriguing abilities of our visual system: how we can interact with, navigate through, and generally understand the 3D world in which we live with such reliability even though the retinal patterns we are given are so disparate and under-constrained.

Short-Term Plasticity, Biophysical Models

Robert Rosenbaum

Department of Applied and Computational Mathematics and Statistics, University of Notre Dame, Notre Dame, IN, USA

Definition

Short-term plasticity refers to changes in synaptic efficacy in response to presynaptic spiking that persist for a few seconds at most but more often decay over a timescale of a few hundred milliseconds. There are two primary types of short-term

plasticity: short-term depression and short-term facilitation. Short-term depression is a reduction in synaptic efficacy that is often, but not always, caused by a transient depletion of neurotransmitter vesicles. Short-term facilitation is an increase in synaptic efficacy often caused by a transient increase in the number of vesicles released by presynaptic action potentials. The detailed biophysical mechanisms underlying synaptic facilitation are discussed in Facilitation, Biophysical Models, and we therefore focus on more phenomenological models of facilitation here.

Detailed Description

Stochastic Models of Short-Term Depression Arising from Neurotransmitter Depletion

Short-term depression is often believed to arise primarily from the depletion of neurotransmitter vesicles, and therefore a large proportion of short-term depression models rely solely on the mechanism of vesicle depletion. It should be noted, though, that some synapses exhibit short-term depression that is inconsistent with vesicle depletion alone (Branco and Staras 2009; Zucker and Regehr 2002; Wong et al. 2003; Xu and Wu 2005).

We begin by describing a model of short-term depression that takes into account the stochastic nature of vesicle release and recovery. The model was introduced in Vere-Jones (1966), and various formulations of it have since been used extensively (Senn et al. 2001; Zador 1998; Wang 1999; Matveev and Wang 2000; Fuhrmann et al. 2002; Goldman et al. 2002; Goldman 2004; de la Rocha and Parga 2005; Pfister et al. 2010; Rosenbaum et al. 2012, 2013, 2014; Reich and Rosenbaum 2013). A presynaptic neuron makes M functional contacts onto a postsynaptic neuron, and each functional contact contains N_0 release sites that can each dock at most one vesicle, so that the maximum number of docked vesicles is $M \times N_0$. Of course, the model can easily be extended to allow heterogeneity in the number of release sites at each contact. Here, the term “functional contact” (hereafter, simply “contact”) refers to a group of vesicle release sites where the grouping

is chosen so that release sites at different contacts release vesicles independently from one another, but release sites on the same contact are not necessarily independent. Functional contacts need not necessarily correspond to anatomical contacts in a one-to-one fashion. The most widely assumed dependence between release sites arises from the “univesicular hypothesis” which states that each contact can release at most one vesicle in response to a single presynaptic spike. If this constraint is to be met, then release sites at the same contact cannot be independent.

Since release sites at different contacts are independent, we need only specify the probability distribution of the number of vesicles released by a presynaptic spike at each contact. A widely used rule (Vere-Jones 1966; Wang 1999; Matveev and Wang 2000; Goldman et al. 2002; de la Rocha and Parga 2005; Rosenbaum et al. 2014) that is consistent with the univesicular hypothesis states one vesicle is released at a particular contact with probability $1 - (1 - p)^n$; otherwise, no vesicles are released. Here p is a number between 0 and 1, and $n \in [0, N_0]$ is a dynamical variable representing the number of docked vesicles at the contact in question at the moment when the presynaptic spike occurs. When $n = 0$, the release probability is zero, as expected. When $n = 1$, the release probability is p . In general, the probability of release increases with the number of docked vesicles.

While the rule above is straightforward to simulate numerically, it is difficult to treat analytically due to the non-independence of release sites. Some analytical tractability can be gained by assuming that the release of a vesicle at each release site is independent. This is equivalent to assuming that each functional contact has exactly one release site (i.e., making the substitutions, $M = M \times N_0$ and $N_0 = 1$). In this widely used version of the model (Zador 1998; Matveev and Wang 2000; Fuhrmann et al. 2002; Goldman 2004; Pfister et al. 2010; Rosenbaum et al. 2012, 2013; McDonnell et al. 2013; Reich and Rosenbaum 2013), each presynaptic spike releases each docked vesicle independently with probability p . Thus, the number of vesicles released by a presynaptic spike is a binomial

random variable with parameters n and p , where n is the number of docked vesicles when the spike arrives.

When a vesicle is released at a contact, the number of docked vesicles at that contact is decremented. The waiting time until a released vesicle is recovered is an exponentially distributed random variable with mean τ_u . Equivalently, it is the waiting time for the first event in a Poisson process with rate $1/\tau_u$. Due to the memoryless property of Poisson processes, this rule allows the modeler to keep track of only the *number* of docked vesicles at each contact and ignore the time at which empty release sites became empty. In particular, the probability that one empty release site is filled during the time interval $(t, t + dt)$, i.e., that the number of releasable vesicles is incremented during that time interval, is given by $(N_0 - n)dt + o(dt)$, where n is the number of docked vesicles at that release site and $o(dt)/dt \rightarrow 0$ as $dt \rightarrow 0$.

Each released vesicle induces a change in conductance of the postsynaptic neuron's membrane. This is often modeled by setting the postsynaptic conductance to $g(t) = \sum_j w_j \alpha(t - t_j)$, where t_j is the time of the j th presynaptic spike, w_j is the number of vesicles released by the j th spike, and $\alpha(t)$ is a stereotyped synaptic conductance waveform representing the change in postsynaptic conductance elicited by the release of a single vesicle. In general, $w_j \in [0, M \times N_0]$ but $w_j \in [0, M]$ whenever the univesicular hypothesis is satisfied.

Pseudo-code for implementing this and similar models of stochastic vesicle dynamics is provided in McDonnell et al. (2013) along with a review and discussion of some effects of stochastic vesicle dynamics on neural coding and the statistics of the synaptic response.

Deterministic Models of Short-Term Facilitation and Depression

The stochastic model of short-term depression discussed above can be difficult to analyze mathematically, and it can also be difficult to fit the model's parameters to data. Moreover, the model assumes that short-term depression is due solely to the depletion of neurotransmitter vesicles even though other factors sometimes play a role.

Finally, the model does not account for the effects of short-term facilitation on synaptic efficacy.

These difficulties are partly overcome by a deterministic model in which synaptic efficacy is treated as an abstract, continuous variable that is modified by each presynaptic spike. This model is mostly agnostic to the precise mechanisms responsible for changes in synaptic efficacy, but it can accurately reproduce experimental data after the model parameters are fit to the data using statistical fitting algorithms. Due to its amenability to mathematical analysis and its ability to reproduce experimental data, this deterministic model and its variations are widely used in both theoretical and experimental studies (Tsodyks and Markram 1997; Varela et al. 1997; Tsodyks et al. 1998; Markram et al. 1998; Chance et al. 1998; Maas and Zador 1999; Fuhrmann et al. 2002; Hanson and Jaeger 2002; Cook et al. 2003; Grande and Spain 2005; Rothman et al. 2009; Lindner et al. 2009; Merkel and Lindner 2010; Pfister et al. 2010; Rosenbaum et al. 2012; Scott et al. 2012; Mohan et al. 2013).

We describe the model as presented in Varela et al. (1997) and then discuss some common variations of the model. The efficacy of a synapse is defined by $A(t) = A_0 F(t) D_1(t) D_2(t) D_3(t)$, where A_0 is a constant representing a baseline efficacy, $F(t)$ is a dynamic variable representing facilitation, and each $D_k(t)$ is a dynamic variable representing depression.

Immediately after each presynaptic spike, each depression variable is updated according to the rule $D_k \leftarrow D_k d_k$ for $k = 1, 2, 3$, where each d_k is a number between 0 and 1 representing the amount of depression evoked by each spike. Between presynaptic spikes, the depression variables decay exponentially back to their maximal values, which can be normalized to one without loss of generality, so that $\tau_{Dk} \frac{dD_k}{dt} = 1 - D_k$, where τ_{Dk} is the timescale of recovery for the k th depression variable.

Similarly, the facilitation variable is updated after each presynaptic spike according to $F \leftarrow F + f$, and the evolution between spikes is defined by $\tau_F \frac{dF}{dt} = 1 - F$.

The postsynaptic conductance (or current for current-based modeling) can then be written in

terms of the synaptic efficacy as $g(t) = \sum_j A(t_j) \alpha(t - t_j)$, where $\alpha(t)$ is a stereotyped waveform and t_j is the time of the j th presynaptic spike.

This model is commonly modified by changing the number of facilitation or depression variables. A common variation uses only one facilitation and one depression variable so that $A(t) = A_0 F(t) D(t)$. Some synapses exhibit short-term depression but not facilitation, in which case the facilitation variable can be removed completely and we can simply write $A(t) = A_0 D(t)$. These two variations of the model are amenable to mathematical analysis (Lindner et al. 2009; Merkel and Lindner 2010; Rosenbaum et al. 2012).

In the form of the model described above, the depression variables are updated multiplicatively, while the facilitation variable is updated additively. Updating facilitation multiplicatively can cause synaptic efficacy to grow unrealistically large at high presynaptic rates (Varela et al. 1997), but a saturating multiplicative update rule was applied in Hanson and Jaeger (2002) and accurately captured recorded data. In other variations of the model, updates to the depression variables depend on the value of the facilitation variables, for example, in Lindner et al. (2009) and Merkel and Lindner (2010), the update rule for the depression is given by, $D_k \leftarrow (1 - F) D_k$.

It should be noted that the deterministic model with one depression variable and no facilitation variables is equivalent to the mean field of the stochastic model of short-term depression with $N_0 = 1$. Specifically, if the stochastic model is simulated over several trials with the same presynaptic spike train, then the trial average of the postsynaptic conductance it produces is proportional to the postsynaptic conductance produced by one trial of the deterministic model driven by the same presynaptic spike train whenever $\tau_u = \tau_D$ and $p_r = d$.

Definition

Short-term synaptic plasticity (STP) is a transient (milliseconds to minutes) activity-dependent change in the amplitude of the postsynaptic current in response to presynaptic activity. Central pattern generators (CPGs) are neural networks in the central nervous system capable of producing coordinated rhythmic output without rhythmic input from sensory organs or from higher control centers.

Detailed Description

Short-term synaptic plasticity (STP) is a transient (milliseconds to minutes) activity-dependent change in the amplitude (strength) of the postsynaptic current in response to presynaptic activity. It has clear implications for neural signaling and has been studied for several decades. Much of the modeling work has focused on the events in the presynaptic terminal and primarily on the role of Ca^{2+} in synaptic release of neurotransmitters (Zucker and Regehr 2002; Fioravante and Regehr 2011). However, postsynaptic effects such as saturation of postsynaptic receptors can also contribute to STP (Hennig 2013; Xu-Friedman and Regehr 2004). A complete understanding of

short-term synaptic plasticity requires knowing how the pre- and postsynaptic neurons interact to alter synaptic strength.

The contribution of short-term synaptic plasticity to network-level output has probably been best examined in studies of central pattern generator (CPG) networks. CPG networks produce rhythmic patterned outputs without patterned input and are best understood in the analysis of rhythmic motor activities such as locomotion and respiration. For instance, the CPG underlying the inspiratory phase of respiration is located in the pre-Bötzinger complex found within the ventrolateral medulla of the mammalian brain (Grillner 2003). Identified CPG circuits are known to govern locomotion in invertebrates, including leeches, mollusks, and crustaceans (Arshavsky Yu et al. 1993; Ayers 2004; Friesen and Kristan 2007). Additionally, locomotion in mammals is believed to be governed by CPG networks in the spinal cord (MacKay-Lyons 2002). The understanding of CPGs in producing motor behaviors has been greatly advanced through the use of computational models (Butera et al. 1999; Tabak et al. 2000; Oh et al. 2012; Vavoulis et al. 2007; Sherwood et al. 2011).

Almost all synapses are regulated by a variety of short- or long-term activity-dependent processes that alter the strength of the synapse. Depending on the behavioral needs, CPGs alter their rhythmic activity patterns by changing the cycle frequency and the relative activity phases of the participating neurons. Synapses in CPG networks are naturally subject to short-term activity-dependent modifications due to the rhythmic nature of the network output. This review examines the mechanisms and consequences of short-term changes in synaptic strength within CPGs. Although both pre- and postsynaptic mechanisms have been implicated in short-term plasticity, the majority of known STP effects are presynaptic (Wadiche and Jahr 2001).

Neurobiology of Central Pattern Generators

CPG networks often involve neurons that produce bursting oscillations. Bursting refers to an interval

of rapid firing of spikes, bookended by intervals of quiescence. Bursting activity in neurons is often the result of a slow-wave oscillation in the membrane potential which, on the depolarized portion, crosses spike threshold. The slow-wave oscillations that underlie bursting activity result from the interaction of low-threshold-activated inward currents and slow voltage- or Ca^{2+} -gated outward currents.

In cases where the mechanisms underlying rhythm generation have been described, CPG oscillations have been shown to arise in one of two ways: either through the activity of endogenously oscillatory (pacemaker) neurons or through the synaptic interactions of neurons within a network (Goldin-Meadow et al. 2001). Pacemaker neurons produce oscillations when they are synaptically isolated from the network. However, these oscillations may be conditional upon the presence of the appropriate neuromodulatory substances. Although pacemaker neurons can be the rhythm-generating kernel of a CPG network, the proper output of the CPG usually requires the synaptic interaction of the pacemaker neurons with non-oscillatory (follower) neurons whose activity is important in producing the proper output pattern.

In contrast to pacemaker-driven CPGs, network oscillators produce rhythmic output through synaptic interactions of pairs or groups of neurons, which may not be oscillatory when synaptically isolated. The most prominent example of such network oscillations is half-center oscillators that drive the activities of antagonistic muscles. First proposed by T. Graham-Brown in the early 1900s, half-center oscillators are responsible for producing rhythmic behavior in these types of networks (Brostoff et al. 2008). Half-center oscillators are driven by neurons (or neuron groups) that are antagonistic in their activity. The two groups of neurons are rhythmically active but activity in one group inhibits the activity of the other. In the first classification of half-center oscillators by Wang and Rinzel, they demonstrated that the transition between the two halves of the half-center oscillation can occur through one of two distinct mechanisms: escape and release. In escape mode, the inhibited neurons transition to

active mode due to their own intrinsic properties. In contrast, in release mode, the active neurons terminated their activity due to their intrinsic properties and thereby release the inhibited neuron which rebounds from inhibition to produce activity (Wang and Rinzel 1992). The frequency and relative phases of the two halves of the half-center are controlled by the intrinsic properties of the neurons as well as the strength and dynamics of the reciprocal synapses. The extent to which intrinsic versus synaptic properties control the half-center oscillations can be used to further divide these networks into intrinsic or synaptic (Skinner et al. 1994). In biological systems, the transitions between the two halves of the half-center oscillator are often through a combination of escape and release mechanisms (Nadim et al. 1995).

Invertebrate CPG studies provided crucial results for the understanding of the mechanisms of neural network connectivity and CPG functions. The ease of accessibility of many of the invertebrate networks has allowed for a mapping of the synaptic connectivity and therefore the identification of the CPG circuits. Additionally, in many invertebrate networks, the voltage-gated ionic currents of the component neurons and the short-term dynamics of the synapses have been characterized. Examples of well-studied invertebrate CPG networks include those underlying tritonia swimming, feeding in crustaceans, and leech heartbeat (Marder and Calabrese 1996).

CPGs have also been the subject of intensive research in vertebrate systems, in particular, lamprey swimming, salamander locomotion, and rodent models of respiration. Lampreys are primitive fish whose spinal cords are easily dissected and are capable of producing fictive locomotion *in vitro*. As such, this preparation has become the best studied example of rhythmic locomotor activity in vertebrates (Grillner 2003). Salamanders offer an insight into the switching of two different types of locomotor modalities: swimming or stepping. Of particular interest is the stepping gait, in which the body makes an S-shape wave with coordinate movement of the limbs (Ijspeert et al. 2007). This stepping gait can either be fast or slow, but salamanders prefer the

faster trotting gait. When trotting, diagonal limbs are in phase while opposite limbs are out of phase. Both the switching between swimming and stepping, as well as the simulation of stepping, have been modeled and studied (Ijspeert et al. 2007) but the full understanding of the behaviors has been elusive.

The medullar pre-Bötzinger complex contains the CPG responsible for the genesis of breathing in mammals (Smith et al. 1991). The pre-Bötzinger complex controls the inspiratory phase of breathing through the activity of a set of pacemaker neurons that are state dependent. In particular, there are two subsets of pacemaker neurons within the system which have been characterized based on their pharmacological properties. During normoxia, respiratory rhythm generation is driven through a heterogeneous population of pacemaker neurons, while during hypoxia the respiratory rhythm is driven by only one type of pacemaker (Pena et al. 2004). The pacemaker groups and the properties of the network have been the subject of many computational models (Butera et al. 1999; Del Negro et al. 2002a, b; Cordovez et al. 2010).

Molecular Mechanisms of Neurotransmitter Release

Presynaptic Machinery Responsible for Neurotransmitter Release

Neurotransmitter release is achieved through the interplay of a variety of proteins associated with the presynaptic terminal. Once transmitter-filled vesicles are transported to the synaptic terminal, they dock and are primed for release. This process involves the attachment of vesicles to the membrane through the SNARE complex, a set of interacting proteins found on the vesicle and cytoplasmic membranes (Jahn and Fasshauer 2012). Only primed vesicles can fuse with the membrane and release neurotransmitter into the presynaptic cleft through the process of exocytosis, triggered by the interaction of Ca^{2+} with the SNARE complex. Depolarization of the presynaptic terminal, usually due to the arrival of an action potential, activates voltage-gated Ca^{2+} channels (VGCCs) and results in a rapid increase of the local

concentration of Ca^{2+} , which then binds to synaptotagmin, causing the vesicle membrane to fuse with the plasma membrane (Mehta et al. 1996). The SNARE complex is a helical protein complex composed of the v-SNARE protein synaptobrevin (also known as vesicle-associated membrane protein [VAMP-2]) and the t-SNARE (“target” SNARE) proteins localized to the presynaptic plasma membrane, SNAP-25 (synaptosome-associated protein of 25 kDa), and syntaxin. Apart from its interaction with v-SNARE, t-SNARE proteins syntaxin also directly interact with the Ca^{2+} channels to promote vesicular fusion (Stanley 1997). Finally, synaptic function also requires the interaction of SNARE proteins with Munc-18, which has been found to allow for syntaxin and SNAP-25 to form a complex that serves as an intermediate in the exocytic pathway (Zilly et al. 2006). The three SNARE proteins, syntaxin, SNAP-25, and synaptobrevin, have been found to be the minimal set of proteins required for fusion (Sudhof 2012).

Pools of Neurotransmitters: Ready or Not

The presynaptic terminal may contain hundreds of neurotransmitter vesicles; however, only a fraction of these, the readily releasable pool (RRP), are docked at the active zones of the membrane awaiting release. The remaining vesicles are divided between the reserve pool, the vesicles that are ready to be moved to the docking position, and the non-recycling pool (Regehr 2012).

Short-term synaptic plasticity is affected by the size of the RRP. The number of vesicles in the RRP varies across species and measuring it could be difficult due to the replenishment from the reserve pool. Earlier studies estimated the range of the RRP to vary from 7 to 130 depending on the type and location of synapse (Rosenmund and Stevens 1996; Xu-Friedman et al. 2001; Zucker and Regehr 2002). However, that number can average as high as 1700 as measured in the mouse neuromuscular junction (Ruiz et al. 2011) and is also high at special high-throughput synapses such as calyx of Held, which contains hundreds of active zones (Schneggenburger et al. 2002). More recent studies have found those numbers to be much smaller than originally estimated.

For instance, at certain GABAergic synapses within the cerebellum, the number of vesicles was found to be maximally 4 (Trigo et al. 2012). The size of the RRP may be regulated by a variety of factors, including the actions of the Na^+/K^+ ATPase pump (Taruno et al. 2012).

Postsynaptic Factors Influence Short-Term Plasticity

While many studies have concentrated on the presynaptic mechanism of short-term plasticity, postsynaptic factors also contribute to changes in the synaptic transmission strength. The postsynaptic response depends on the amount of transmitter release from the presynaptic neuron, kinetics of the receptor, and other factors. Postsynaptic Ca^{2+} contributes significantly to post-tetanic potentiation in sensory-motor neurons of Aplysia, by facilitating the induction of plasticity at neighboring neurons (Schaffhausen et al. 2001). Additionally, when postsynaptic receptors are saturated, this may limit responses by the cell, as shown at the climbing fiber synapse (Wadiche and Jahr 2001). Desensitization of postsynaptic receptors can cause a temporary decrease in synaptic responses (Xu-Friedman and Regehr 2004). Additionally, saturation of the postsynaptic receptors may have a significant impact on recovery from depression (Foster et al. 2002).

The Role of Ca^{2+} in Neurotransmitter Release
 Ca^{2+} entry through VGCCs in the presynaptic terminal results in vesicle fusion and the release of neurotransmitters. Synaptic strength is dependent on Ca^{2+} levels in the presynaptic active zone. This is believed to be partially due to Ca^{2+} interaction with multiple low-affinity binding sites on synaptotagmin, several of which have to be bound to trigger vesicle fusion (Felmy et al. 2003). If Ca^{2+} binds one or more sites, it increases the probability of release upon subsequent depolarization of the presynaptic membrane. Elevated amounts of local Ca^{2+} , however, are transient and highly sensitive to the distance from the VGCCs and the site of release. Local Ca^{2+} concentrations are also affected by Ca^{2+} -binding proteins that exist in the presynaptic bouton (Regehr 2012). Not all Ca^{2+} that enters the presynaptic

cell, however, binds to the docked vesicles: it diffuses away from the active site, is rapidly buffered (Burrone et al. 2002; Burnashev and Rozov 2005), or is actively pumped out of the presynaptic terminal (Regehr 2012). The residual Ca^{2+} is then gradually removed from the presynaptic bouton (Scott and Rusakov 2006). Ca^{2+} diffusion in the presynaptic terminal has been extensively studied and modeled (Simon and Llinas 1985; Zucker and Fogelson 1986; Bertram et al. 1999; Matveev et al. 2004).

Multiple Forms of Synaptic Plasticity Coexist at a Synapse

The interactions of different types of synaptic plasticity found at most synapses allows for an alteration in synaptic strength. Short-term depression, facilitation, augmentation, and post-tetanic potentiation can coexist at the synapse; however, the dominance of each of the mechanisms at a given time point is controlled by the activity of the presynaptic neuron.

Short-term plasticity is often measured using a paired-pulse protocol. The presynaptic neuron is stimulated with a square pulse two to five times with an appropriately chosen interpulse interval. The postsynaptic response is then measured for each stimulus and the ratio of the postsynaptic response to the presynaptic response becomes the measure of short-term plasticity. If the ratio is greater than 1, the response is deemed facilitatory, and when it is less than 1 then it is deemed depressing. This method has been used in a variety of systems including different CPGs such as the pre-Bötzinger complex, the pyloric network of the stomatogastric system, and leech feeding behavior.

Facilitation

Synaptic facilitation is a type of short-term plasticity where the amount of neurotransmitter released is increased during a sequence of action potentials reaching the synaptic bouton. This increase leads to a prolonged effect of the neurotransmitter on the postsynaptic membrane. This type of short-term plasticity occurs at the fastest

time scale and is measured using a paired-pulse protocol. Facilitation is subdivided into two different stages: F1 facilitation which lasts tens of milliseconds and F2 facilitation which lasts hundreds of milliseconds (Zucker and Regehr 2002).

Many ideas were put forward to explain presynaptic facilitation (Regehr 2012). The simplest hypothesis states that the arrival of the action potential at the presynaptic bouton evokes a rise in local Ca^{2+} which triggers neurotransmitter release and which then persists at a lower concentration in the presynaptic bouton. Since such low residual Ca^{2+} concentration is insufficient by itself to trigger low-affinity vesicle release gates, this hypothesis requires the residual Ca^{2+} to act at a high-affinity presynaptic Ca^{2+} sensor other than synaptotagmin. Further, such a high-affinity second sensor should be located farther from the channel in order to prevent its rapid saturation; for this reason, this model is sometimes referred to as the two-site model of synaptic facilitation (Matveev et al. 2002) (Fig. 1a). A second possibility is that this second, high-affinity Ca^{2+} binding site possesses slower Ca^{2+} kinetics, allowing its Ca^{2+} -bound state to outlive the Ca^{2+} residual signal. This mechanism is often referred to as the bound residual Ca^{2+} mechanism of synaptic facilitation (Matveev et al. 2006) and was historically the first facilitation model proposed in the pioneering studies by Katz and Miledi (1968), who called such bound Ca^{2+} the “active” Ca^{2+} (Bornschein et al. 2013; Isope 2013). Finally, it is also possible that this additional slower Ca^{2+} binding process may represent Ca^{2+} -dependent vesicle priming or other Ca^{2+} -dependent process upstream of vesicle (Pan and Zucker 2009).

The action of endogenous Ca^{2+} buffers has been proposed as an alternative mechanism of synaptic facilitation. Both fast, high-affinity Ca^{2+} buffers and those that slowly bind Ca^{2+} can influence facilitation. Ca^{2+} binding proteins reduce the concentration of local Ca^{2+} at the release site (Regehr 2012). However, high-affinity Ca^{2+} buffers bind Ca^{2+} at the presynaptic bouton when concentrations are sufficiently high, which leaves them unable to bind additional Ca^{2+} . As a result, the additional Ca^{2+} that enters and is not bound by buffers will reach the release site. In this

Short-Term Synaptic Plasticity in Central Pattern Generators, Fig. 1 *Models of facilitation (a) Residual-free Ca^{2+} accumulation: the two-site model of synaptic facilitation.* Exocytosis requires simultaneous binding of Ca^{2+} (red circles) to a low-affinity sensor located within the channel nanodomains (magenta at the vesicle base) and more remotely located low-affinity sensors (blue on the far side of the vesicle). The accumulation of free residual Ca^{2+} is small but more significant far from the channel, allowing for a significant increase in the binding of remote Ca^{2+} sensor from the first stimulus to the second and, therefore,

more transmitter release and a larger postsynaptic response (*bottom traces*). (b) *Facilitation by saturation of high-affinity buffer.* The postsynaptic response (*bottom trace*) to the first presynaptic stimulus is small, because most of the free Ca^{2+} ions entering the presynaptic site are bound (yellow circles) by the Ca^{2+} buffer molecules (blue crescents) before they reach the vesicles. However, the postsynaptic response to the second presynaptic stimulus will be large because there are fewer free buffer molecules around, thus increasing the probability of Ca^{2+} ions reaching the targets for exocytosis

manner, local buffer saturation can contribute to paired-pulse facilitation (Burnashev and Rozov 2005; Matveev et al. 2006; Neher 1998) (Fig. 1b). Slow Ca^{2+} binding proteins can also influence facilitation. By controlling the concentration of residual Ca^{2+} and accelerating its decay in the presynaptic bouton, slow endogenous buffers act like the slow buffer EGTA (Atluri and Regehr 1996), which then provides a mechanism to control the rate of Ca^{2+} decay, thereby influencing facilitation rates (Regehr 2012). However, the contribution of both fast and slow buffers to facilitation is still a matter of debate (Bornschein et al. 2013).

An important example of a CPG where synaptic facilitation has been observed and studied both experimentally and using computational modeling is the lamprey swim CPG. In control conditions, activity-dependent plasticity does not contribute to the patterning of network activity. However, Kozlov et al. found that substance P can lead to an activity-dependent facilitation during repetitive activation of the inhibitory cross caudal interneurons (CCINs) in the lamprey swim CPG (Parker and Grillner 1999; Kozlov et al. 2001). This is accomplished through control of the

release of the neuromodulators from the presynaptic side as well as postsynaptic modulation of different ionic conductances (Kozlov et al. 2001). In order to examine the activity-dependent facilitation in this system, they used a compartmentalized Hodgkin-Huxley model neuron with the synaptic activation modeled as a leaky integrator and synapse activation summing input spike events of constant duration. Their study aimed to elucidate the two alternate modes of activity within the lamprey spinal locomotor network, showing that facilitation has a strong effect on frequency regulation in this CPG (Kozlov et al. 2001).

Facilitation has also been observed in the crustacean stomatogastric nervous system, specifically in the synapses of the pyloric CPG. The synapse from the lateral pyloric (LP) neuron to the pyloric dilator (PD) neurons is the sole chemical feedback to the pacemaker group and exhibits short-term depression. This synapse possesses both a graded and spike-mediated component (Zhao et al. 2011). However, the presence of the endogenously released neuromodulatory peptide proctolin switches the dynamics of this synapse from depression to facilitation. The mechanism of

this switch was investigated in the modeling study of Oh et al. (2012), who proposed that the low-voltage-activated Ca^{2+} current possesses both fast and slow kinetic components and that proctolin adjusts the activation rate of the slow component, leading to an accumulation of local Ca^{2+} in response to low-voltage presynaptic stimuli, resulting in synaptic facilitation (Oh et al. 2012).

Depression

At many synapses, elevated activity or repeated stimulation leads to a decrease in synaptic strength. As is the case for facilitation, multiple mechanisms can contribute to synaptic depression (Zucker and Regehr 2002; Regehr 2012). Depression is believed to be caused in large part by the reversible depletion of available synaptic resources, mainly the release-ready pool of vesicles (RRP; Fig. 2a). Such vesicle depletion is an example of use-dependent synaptic depression, with higher levels of use associated with larger degree of synaptic depression (Markram et al. 1998). Reducing the level of synaptic transmission relieves use-dependent synaptic depression, while at high sustained synaptic activity, the replenishment of the RRP from the reserve vesicle pool cannot keep up with the depletion of the RRP (Zucker and Regehr 2002; Regehr 2012). Therefore, the extent to which depletion occurs is

dependent on the number of vesicles in the RRP at each active zone and the number of vesicles that are released by an action potential. This depletion model accounts for the properties of the paired-pulse depression that is seen in many different types of synapses. According to the depletion model, the more vesicles released with the initial stimulus, the fewer will be released by the second and subsequent pulses. Depression by vesicle depletion is particularly pronounced following high-frequency tetanic stimulation, which strongly depletes the RRP so that the subsequent recovery may take tens of seconds, rather than seconds.

Another mechanism of activity-dependent depression involves inhibition of the response caused by the vesicle fusion with the active zone. Vesicle fusion may transiently disrupt the morphology of the active zone and may inhibit the time it takes for membrane proteins to clear the active zone. This mechanism is supported by experimental evidence that blocking endocytosis can increase synaptic depression during pulse trains (Regehr 2012).

Other depression mechanisms may depend on the intensity of stimulation rather than amount of neurotransmitter released. This is true, for instance, in the case of inactivation of Ca^{2+} channels that has been found to account for depression

Short-Term Synaptic Plasticity in Central Pattern Generators, Fig. 2 Models of depression (a) **Synaptic depression by vesicle depletion.** The postsynaptic response (bottom panel) to the second presynaptic stimulus is greater compared to the response to the first presynaptic stimulus because of the reduction in the number of available neurotransmitter-filled vesicles (green circles). (b) **Ca^{2+} channel inactivation/presynaptic modulation.**

Presynaptic Ca^{2+} channel opening probability may decrease during the presynaptic stimulus train, due to one of two mechanisms: (i) inactivation of presynaptic voltage-dependent Ca^{2+} channels or (ii) activation of presynaptic metabotropic receptors that modulate the gating of presynaptic Ca^{2+} channels (e.g., through G-protein-regulated pathways). Reduction in the presynaptic Ca^{2+} current leads to a reduction in the vesicle release rate

at some synapses (Bertram et al. 2003). Presynaptic recordings from the calyx of Held have shown that high-frequency stimulation reduces Ca^{2+} entry. Decreased Ca^{2+} entry was found at frequencies greater than 30 Hz and depletion was found when the stimulus was in excess of 100 Hz (Xu and Wu 2005).

Also on the presynaptic side, depression can arise through the activation of metabotropic presynaptic receptors activated by modulatory substances released from the activated presynaptic terminals, postsynaptic cells, or neighboring cells (Fig. 2b). Metabotropic receptors may be selective either for the neurotransmitter released by the terminal itself (autoreceptor-mediated depression), for retrograde messengers (e.g., endocannabinoid receptors), or for neuromodulatory substances projecting from elsewhere in the nervous system (neuromodulatory receptors). Depression may also arise from postsynaptic mechanisms such as postsynaptic receptor desensitization, which in fact represents another form of use-dependent synaptic depression. Another mechanism of synaptic depression was demonstrated in the developing spinal cord (Tabak et al. 2000, 2001). In this system, GABA is functionally excitatory because intracellular Cl^- is high. During an episode of activity, Cl^- ions leave the neurons so the GABA reversal potential becomes more negative. This mechanism seems quite important for the episodic activity in the developing spinal cord.

Regulation of and recovery from depression are also important factors in short-term synaptic plasticity. Bassoon, a large presynaptic protein present at the active zone, has been found to minimize depression by replenishing vesicles at release sites (Hallermann et al. 2010; Regehr 2012). When Bassoon is experimentally removed, synaptic depression is enhanced. Rab3-interacting molecules (RIM) are vital components of the active zone (Kaeser et al. 2011), serving two critical functions: priming of synaptic vesicles and tethering of Ca^{2+} channels to the active zone (Kaeser 2011; Kaeser et al. 2011). RIM proteins have been implicated in influencing depression: when they are removed, depression is dramatically alleviated (Calakos et al. 2004; Sudhof 2012).

The role of synaptic depression in CPG networks has been studied in great detail. For instance, synaptic depression has been determined to be pivotal in the maintenance of phase relationships within CPGs (Mamiya et al. 2003; Manor et al. 2003). Depression of synapses of the pyloric network leads to synaptic weakening during fast rhythmic behavior while allowing the synapses to remain strong during a slow rhythm (Marder et al. 2005). Manor et al. examined the effect of synaptic depression using a model of an oscillator neuron and a follower neuron coupled with an inhibitory synapse from the oscillator to the follower (Manor et al. 2003). An important result from their study was that depression in inhibitory synapses always promotes a constant relative phase between the pre- and postsynaptic neurons in an oscillatory network. The strength of a depressing synapse in an oscillatory network is dependent on the cycle frequency: the faster the oscillation, the more depression and therefore the weaker the synapse. This frequency dependence implies that synaptic inhibition gets weaker if the network operates at a faster pace, thus reducing the latency between the pre- and postsynaptic neuron activity. Because relative phase is defined as latency over period, this simple observation implies that a depressing synapse will always promote phase constancy (as opposed to a constant latency) compared to a synapse that is nondepressing.

In order to maintain stability, a network may reconfigure itself to produce different patterning behaviors. Li et al. explored the mechanisms by which sensory activity led to the selection and generation of swimming and struggling in *Xenopus* tadpoles (Li et al. 2007). In *Xenopus* tadpoles, two different behaviors can be triggered: struggling, which is elicited if the animal is held or pinned against a silicone-gel-lined Petri dish and involves strong head-to-tail bends, and swimming, which is elicited if the animal is touched lightly and involves low-amplitude bends (Kahn and Roberts 1982; Li et al. 2007). In immobilized tadpoles, stimulation of the skin causes a switch of the struggling CPG by reconfiguration of the locomotor network. This switch is thought to be caused by a context-dependent short-term

depression of the reciprocally inhibitory synapses between two CPG neurons, the commissural interneurons (cINs). When synaptic depression was included in these synapses in a model network, activation of the network at higher firing frequencies characteristic of struggling led to robust bursting activity. In contrast, when the network was activated at lower firing rates, depression was not active and the network output resembled more the swimming behavior which involves a single spike per cycle (Li et al. 2007). Thus, as shown in this system, synaptic depression of reciprocal inhibition may play a key role in one behavior (struggling) but be mostly absent in another (swimming).

Synaptic depression was also proposed as the principal mechanism of rhythmogenesis in the developing chick spinal cord (Tabak et al. 2000). These studies proposed that synaptic depression accumulates during the active burst phase of the rhythm, ultimately terminating the active phase, and that the recovery from depression during the inactive state allows the bursting activity to resume in the next cycle of activity. Within certain networks, rhythm generation may depend on specific types of synaptic depression which are more complex than simple vesicle depletion. For example, this is the case in the group pacemaker model of rhythmic activity in the pre-Bötzinger complex developed by Rubin et al. (2009) based on a Hodgkin-Huxley style conductance-based model of spiking activity. In this model, glutamatergic synapses and short-term depression of excitatory transmission have roles in the rhythmogenesis of a particular type of pacemaker group within the pre-Bötzinger complex. A network-wide burst is generated through recurrent synaptic excitation that initiates the postsynaptic Ca^{2+} -activated non-specific cation current (I_{CAN}). The depolarization due to I_{CAN} causes a voltage-dependent spike inactivation, diminishing recurrent excitation and therefore attenuating the postsynaptic accumulation of Ca^{2+} . The burst is then terminated through activity-dependent outward currents, resulting in a quiescent state in the network. A new cycle is then initiated when sporadic spiking activity rekindles excitatory interactions (Rubin et al. 2009).

Augmentation and Post-Tetanic Potentiation

While facilitation has been shown to last no more than hundreds of milliseconds, two other forms of potentiating short-term synaptic plasticity, last tens of seconds to minutes in duration. Augmentation and post-tetanic potentiation (PTP) are related forms of synaptic plasticity that are observed after sustained high-frequency stimulation (Zucker and Regehr 2002; Regehr 2012). Augmentation is an increase in the synaptic potential amplitude that is produced by repetitive stimulation which has been found to act by potentiating vesicle fusion (Zucker and Regehr 2002). Post-tetanic potentiation is a common form of short-term plasticity that leads to an increase in synaptic strength for several minutes after increased stimulation. PTP is closely related to augmentation and lasts tens of seconds to minutes in duration and increases with the presence of additional or sustained stimuli.

Augmentation was originally described in the frog neuromuscular junction and now has been observed in many synapses, including in mammalian cortex (Regehr 2012). Augmentation increases during a stimulus train, but decays slower than facilitation with a time constant of 5–8 s. The decay of augmentation has been shown to be insensitive to stimulation duration and frequency. Additionally, augmentation shares other properties with facilitation. Augmentation is dependent on the buildup of Ca^{2+} in the presynaptic terminals during spike trains, after the development of a significant level of facilitation. Several mechanisms are believed to contribute to augmentation and PTP, including action potential broadening, increase in quantal size, and changes in the RRP (Zucker and Regehr 2002).

Several functional roles of augmentation and PTP in synaptic plasticity have been suggested. Augmentation is believed to be a counteracting mechanism against depression during times of high levels of neural activity (Deng and Klyachko 2011). Furthermore, it has been shown that transmitter release is sustained during trains of stimuli by increasing the release probability of vesicles within the RRP. In addition to maintaining transmitter release during high-frequency stimulation, augmentation has been found to directly

counteract depression in hippocampal excitatory synapses (Deng and Klyachko 2011). The mechanisms for both augmentation and PTP have been studied and debated for many years. Early studies proposed the accumulation of residual Ca^{2+} as a primary mechanism, but more recent results have implicated both PKC activation and CaM kinase II activity (Hennig 2013). However, very few studies have concentrated on these phenomena in CPGs.

In the crustacean STG, the gastric mill network is responsible for movement of muscles that control chewing within the foregut. Stein et al. characterized the temporal dynamics of the gm6 gastric mill muscle and explored the response of this muscle to different patterns of input during the gastric mill CPG activity (Stein et al. 2006). Using train stimulations of various frequencies, they found that augmentation increased the amplitude of the EJPs at certain frequencies while not at others. During the ongoing gastric mill rhythm, augmentation contributed to the response of the muscle as well as muscle force.

Outlook

Theoretical models have contributed greatly to the advancement in understanding of synaptic transmission and short-term plasticity in CPGs. In concert with experimental data, studies of both vertebrates and invertebrate CPGs have provided insight and mechanisms by which neural circuits reconfigure in order to generate different patterns to alter behavior. Many of the models discussed capture the processes involved in short-term synaptic release in a relatively simple way. Additionally, many studies on the effects of short-term synaptic plasticity on CPG activity suggest that neuromodulators play an important role in the network behavior through their effects on synaptic properties. As CPG circuits continue to be mapped, it will be essentially to gain insight about mechanisms which cause switches in behavior, changes in synaptic strength, and remodeling of the circuits in general. The mutual relationship between computational modeling and experimental studies will continue to be important for the understanding of the role of STP in CPG function.

Signaling Pathways, Modeling of

Jeanette Hellgren Kotaleski
School of Computer Science and
Communication, KTH Royal Institute of
Technology, Stockholm, Sweden

Synonyms

[Kinetic modeling](#)

Definition

The use of models to study the dynamical behavior of a biological (sub)system described as a set of biochemical reactions and diffusion. Here, the evolution in time for quantities such as protein concentrations or amount of enzyme activation is typically described using ordinary differential equations. The evolution in time of second messengers is typically described using partial differential equations. Alternatively, stochastic methods can be used to determine evolution in time of all molecules in a simulation.

Detailed Description

The development of quantitative models at multiple spatial and temporal scales is necessary for integrating the knowledge obtained from diverse experimental approaches into a coherent picture. Such models represent current knowledge in a compact and standardized way and constitute a tool for guiding experiments and generating predictions.

Modeling of intracellular signaling within the field of computational neuroscience is typically done to better understand how events on the subcellular level affect, or even may explain, higher-level phenomena. For example, subcellular mechanisms underlying synaptic long-term potentiation (LTP) and long-term depression (LTD) could be investigated in models of receptor-induced cascades of signaling molecules activated during typical experimental protocols. Commonly modeled LTP or LTD systems begin with the activation of transmembrane receptors or the influx of calcium and include the activation of kinases and/or phosphatases and their phosphoprotein targets (see, e.g., Kotaleski and Blackwell 2010).

Dynamical modeling of signaling pathways is required because steady states are rarely achieved. Most of the time activation of signaling pathways is transient, and thus, the response of the system is transient. Intracellular signaling pathways may reach a steady state solution if the activation is kept constant, but sometimes such systems can show oscillations or behave as a bistable (or even multistable) biochemical switch.

How to Represent the Reactions in the Signaling Pathway?

Signaling pathways are represented as cascades of biochemical reactions, together with the diffusion of a subset of the molecular species. It is not plausible to include every reaction known to occur in neurons or cells; thus, the modeled pathway includes those components, such as enzymes, proteins, calcium ions, etc., judged to be relevant for the research question. The identification of critical components and how they interact or react typically are based on experimental data. Such data is often qualitative, but quantitative data are required for model development. Once the relevant molecules and reactions have been identified, the system can be specified and simulated. Two general approaches to the simulations are *stochastic* and *deterministic*. When using a deterministic approach, the system of biochemical reactions are described using a system of ordinary differential equations, which describe the rate of change in the concentrations/amounts of each component. The rate of change is based on the concentrations of all other reactants involved in a reaction. In addition, the *diffusion* of molecules is represented using discretized versions of partial differential equations. Various software packages that include numerical integrators can then be used to simulate the dynamics of the system if initial conditions and reaction rate parameters are provided.

To capture the individual steps in a signaling pathway, bimolecular and enzymatic reactions as well as protein modifications need to be included. Simple biochemical reactions, where one reacting substance (A) binds to another one (B) to form a product (AB) or to modify each other (A^* , B^*), can be represented as

Here, it is assumed that in both these cases, the reaction can be reversed. The speed of the forward and backward reactions is described by corresponding reaction rate parameters, k_f and k_b .

The “ $A + B \leftrightarrow AB$ ” system in Eq. 1, for example, is modeled deterministically using the following first-order differential equations:

$$\begin{aligned} d[A]/dt &= d[B]/dt \\ &= -k_f \cdot [A] \cdot [B] + k_b \cdot [AB] \text{ and } \end{aligned} \quad (3a)$$

$$d[AB]/dt = k_f \cdot [A] \cdot [B] - k_b \cdot [AB], \quad (3b)$$

where $[A]$, $[B]$, and $[AB]$ stand for the concentrations (e.g., measured in μM) of the corresponding reactants or products. The k_f and k_b rate parameters have here units of $\text{concentration}^{-1} \text{time}^{-1}$ and time^{-1} , respectively. The units for concentration of molecules must match the units of the rate constants. One additional set of values are required: given the initial concentrations for A , B , and AB , one can numerically integrate the behavior of the system over time.

When the system Eq. 1 above has reached steady state, ss , so that all time derivatives of the concentrations are zero, then

$$k_b/k_f = [A_{ss}] \cdot [B_{ss}]/[AB_{ss}], \quad (4)$$

where k_b/k_f defines the dissociation constant, K_D , which thus can be estimated from the steady state concentrations of the involved species. (Note that sometimes the affinity constant, $K_A = 1/K_D$, is given instead.) Measures of K_D are provided in the biochemical literature more frequently than individual rate constants, because to estimate k_b and k_f individually requires data on the dynamics in the system, which are difficult experiments to perform.

The above approach assumes *mass action kinetics* which states that the rate of a reaction is the product of a rate constant (k) times the concentrations of the reacting species. This approach can be used to describe the behavior of both reversible and irreversible reactions, also when these reactions are part of reaction cascades, such as simple enzymatic reactions, as explained below. A similar framework, $A \leftrightarrow A^*$, can also represent the exchange of mass through diffusion between different compartments (dendritic spines, dendritic shaft, or different subvolumes within a spine or a dendrite). The rate by which the species move between

compartments can be represented by the diffusion coefficient adjusted for the volume and contact areas of the adjacent compartments.

Mass action kinetics grew out of the work by Guldberg and Waage (reviewed by Lund 1965) who investigated, and tried to find laws for, how the velocity of chemical reactions could be described. This law describes how fast the molecules in a well-stirred solution collide and interact on average (and thus, stochastic interactions between individual species molecules are ignored).

Enzymatic reactions can be modeled as a cascade of biochemical reactions with the approach above. Enzymes speed up the rate by which the substrate of the enzyme is transformed into a product. The underlying reactions are assumed to be captured by the following scheme, which in the simplest case assumes a nonreversible catalytic step, a scheme developed successively in the early twentieth century by Michaelis and Menten (1913) and Briggs and Haldane (1925):

In the first step, described as above by a k_f and k_b rate parameter, the enzyme (E) binds to the substrate (S) in an enzyme-substrate compound (ES). The second reaction step, where the enzyme is catalyzing the formation of the product, is controlled by the catalytic rate parameter, k_{cat} . Again, given some initial conditions and some values on the rate parameters, k_f , k_b , and k_{cat} , these two reaction steps can be modeled *deterministically* using first-order differential equations of the form

$$\begin{aligned} d[E]/dt &= -k_f \cdot [E] \cdot [S] + k_b \cdot [ES] + k_{cat} \\ &\quad \cdot [ES] \end{aligned} \quad (6a)$$

$$d[S]/dt = -k_f \cdot [E] \cdot [S] + k_b \cdot [ES] \quad (6b)$$

$$\begin{aligned} d[ES]/dt &= k_f \cdot [E] \cdot [S] - k_b \cdot [ES] - k_{cat} \\ &\quad \cdot [ES] \end{aligned} \quad (6c)$$

$$d[P]/dt = k_{cat} \cdot [ES] \quad (6d)$$

A common example is the reaction catalyzed by a kinase, which phosphorylates a substrate,

$S + \text{ATP} \rightarrow P + \text{ADP}$, where the substrate, S , is a protein to be phosphorylated, P . This simple, one-step reaction assumes that ATP is constant (and sufficiently high that it is not rate limiting) and all substrate molecules have formed a complex with the enzyme. Then, the reaction rate is captured by the k_{cat} rate constant above. In theory, an enzymatic reaction must be reversible since an enzyme just speeds up the reaction, but does not change the steady state, which is decided by the thermodynamics constraints. Thus, if the product is accumulating in high enough amounts, a reversible reaction may need to be accounted for. Whether this needs to be represented in a model depends on the equilibrium constants for the enzymatic reactions considered.

Enzymatic reactions are sometimes modeled deterministically using the *Michaelis-Menten kinetics*. With this simplification, the variations in $[E]$ and $[ES]$ are discarded from Eq. 6a–6d and instead assumed to be constant, i.e., $d[ES]/dt = 0$, as during steady state conditions. Since the amounts of the substrate and product change over time, this assumption requires that the substrate be present in sufficient amount, else the amount of $[ES]$ will change over time. Whether the enzymatic reaction can be simplified to the Michaelis-Menten (MM) formalism or needs to be modeled explicitly using Eq. 6 depends therefore on the particular system modeled.

When modeling a set of signaling pathways as a cascade of biochemical reactions, the product of one reaction is usually the substrate of a subsequent reaction. Alternatively, active enzymes are often the product of a reaction. Frequently, enzyme and bimolecular reactions alternate. For example, first a ligand binds to a receptor; second, the ligand receptor complex is an enzyme; third, product of the enzyme reaction binds to and activates another enzyme, etc. When the product of the enzyme is a diffusible molecule, it is often called a second messenger. The diffusion and degradation of the second messenger must be modeled carefully to correctly represent its spatial and temporal dynamics.

When searching for parameter values in the literature for the various enzymatic reactions to

be represented in the model, usually only k_{cat} (or more often V_{max} which is k_{cat} total amount of enzyme) and the concentration of substrate when the production of product is half-maximal, K_M , is reported. Thus, the k_f , k_b , and k_{cat} in the equations above need to be mapped onto K_M , and it can be shown that $(k_b + k_{\text{cat}})/k_f = K_M$. This, however, means that we only have two measured values but three parameters to set. Thus, when k_b is not known explicitly, it needs to be set, e.g., as $4 \cdot k_{\text{cat}}$ as motivated in Bhalla and Iyengar (1999). Under the assumption that $d[ES]/dt = 0$, and setting $[E] = [E_{\text{total}}] - [ES]$, then

$$d[P]/dt = k_{\text{cat}} \cdot [E_{\text{total}}] \cdot [S]/(K_M + [S]) \quad (7)$$

Whether the Michaelis-Menten (MM) representation, Eq. 7, and the explicit formulation above, Eqs. 6a–6d, give similar results or not depends on to what extent the assumptions underlying the MM formalism are fulfilled. In, e.g., Ramakrishnan and Bhalla (2008), there is one example of a minimal biochemical system that can behave as a switch when the system is modeled using the MM formalism, but not when the explicit formulation above is used.

Limitations

Although the above deterministic approaches are commonly used within the computational neuroscience field (Manninen et al. 2010), several factors should be considered when representing a signaling pathway with a set of ordinary differential equations, assuming well-stirred solutions. For example, receptor-induced cascades involved in synaptic plasticity typically are localized in dendritic spines, and compartmentalization with regard to functions of different molecules might be common. Also proteins are heterogeneously distributed in different parts of the cytosol and membrane, and some molecules are anchored, while others might diffuse freely. Modeling these reactions across different compartments requires diffusion. If reacting or diffusing species are present in small quantities, then reactions and diffusion occur stochastically, in which case they

cannot be modeled deterministically, and stochastic approaches must be used.

One overall challenge when building models of signaling pathways is the estimation of the reaction rate constants and amounts of the different molecular species. Biochemical estimates of model parameters can, for instance, be obtained through “test tube” experiments. However, the conditions in real cells might vary significantly from those in the experiments.

Although one often talks about a signaling pathway, it should be realized that such a reaction cascade is most likely embedded in a larger signaling network and that many interactions from other parts of the bigger system are left out. This also makes it difficult to validate pathways models, e.g., a pathway leading from a certain G-protein-coupled receptor to the activation of an enzyme, if those pathways are present in different cell types. Although the reaction rates between the pathway’s individual components are assumed to be similar, differences in the left-out interacting network might affect effective concentrations of enzymes and substrates through sequestration effects, for example, through the competition for available pools of enzymes and substrates.

Significance Evaluation

Matthew T. Harrison
Division of Applied Mathematics, Brown
University, Providence, RI, USA

Synonyms

[Hypothesis testing](#); [p-value](#); [Statistical significance](#)

Definition

Broadly speaking: assigning a numerical score to the “unusualness” of data relative to a specific theory. In this entry: computing a p-value for a statistical hypothesis test with emphasis on spike-train resampling.

Detailed Description

Deciding whether the patterns observed in experimental data support or challenge existing theories is a recurring theme in data analysis. Assigning a numerical score, or *significance*, is a central part of the decision process. *Hypothesis testing* is the classical statistical approach with *p-values* being the most common (but not the exclusive) method of communicating statistical significance. This entry is about basic statistical hypothesis testing with a focus on the connection between hypothesis testing and the so-called resampling methods that are gaining widespread popularity in the statistical analysis of neural firing patterns.

A comprehensive statistical analysis rarely stops with hypothesis testing. Parameter

estimation and confidence intervals are often more useful statistical tools. This entry, however, focuses exclusively on hypothesis testing and, in particular, on p-values. (Bayes factors and more generic model selection tools are not discussed.) Although hypothesis testing may not be the ending point of data analysis, it is often an insightful starting point and typically requires simpler statistical models and methods than a more complete analysis.

Statistical Versus Scientific Significance

Statistical significance should never be equated with scientific or experimental significance. Although establishing statistical significance may be an important prerequisite for establishing scientific significance, the latter requires additional analyses, interpretations, and, quite often, experiments. Statistical significance tries to quantify how unusual the data appear with respect to a given statistical model. If the statistical model is not appropriate for the experimental question or if the measured effect is too small to be of scientific importance, then statistical significance, no matter how striking, may have little or no scientific significance. This entry is about *statistical significance* only.

Hypothesis Testing and p-Values

Hypothesis testing begins with a null hypothesis H_0 which can be viewed as a collection of hypothesized probability distributions for the data. Often, H_0 is specified in two steps. The first step involves various underlying *modeling assumptions*, such as the data consist of n independent coin flips with a common probability θ of observing a head on each flip. The second step involves additional restrictions within this basic modeling paradigm, such as the probability, θ , is exactly one-half, which might be written as

$$H_0 : \theta = 0.5.$$

Or, for another example, the null hypothesis might be that the coin is biased towards heads, namely,

$$H_0 : \theta > 0.5.$$

When interpreting the conclusions of a hypothesis test, it is important to inspect both the obviously stated null hypothesis (such as $\theta = 0.5$) and the sometimes not-so-obvious modeling assumptions (such as independent coin flips or constant θ) for their fidelity to the scientific questions at hand.

In most cases, a hypothesis test also comes equipped with a *p-value*. A p-value is any function of the data, say $p(X)$, where X is the data, with the property that

$$\begin{aligned} \text{Prob}(p(X) \leq \alpha) &\leq \alpha \text{ for all } 0 \leq \alpha \\ &\leq 1 \text{ whenever } X \text{ satisfies } H_0, \end{aligned} \quad (1)$$

where $\text{Prob}(A)$ denotes the probability of the event A – in this case, the event that the p-value is at least as small as the number α . Loosely speaking, if the null hypothesis is true, then it is unusual to see a small p-value. For instance, the probability of seeing a p-value less than 0.1 is at most 10% when H_0 is true.

Sometimes, we redundantly say that a p-value is *valid* to emphasize that it has property (1) and to distinguish it from other objects, such as approximations of p-values, that might be (mis-)interpreted as p-values or mistakenly called p-values, even though they are not valid p-values. For any given null hypothesis, there will be many potential ways to create a p-value. It is extremely important to decide which type of p-value will be used before observing the data; otherwise, the “p-value” will lose its validity and will not satisfy property (1) – it will no longer be a p-value! (See section “[Choice of \$T\$ and the Alternative Hypothesis](#)”.)

P-values are particularly useful for communicating statistical significance, because they have a common interpretation regarding type I error rates. A *type I error* occurs when we reject a null hypothesis even though it is true. P-values have the nice property that if we pick a threshold, say 0.05, and reject null hypotheses whenever the corresponding p-values are 0.05 or less, then our

type I error rate is at most 5%. Similarly, if we use a threshold of 0.01, then our type I error rate is at most 1%. In light of these formal guarantees, it is commonplace for smaller p-values to be interpreted as stronger statistical evidence against the null hypothesis than larger p-values.

When the null hypothesis is true, p-values tend to not be small. For a p-value to be useful, however, it should also have good *power*, meaning that it does tend to be small when the null hypothesis is false and some competing alternative hypothesis is true instead. The *alternative hypothesis* is a different collection of hypothesized probability distributions for the data that is distinct from the collection defined by H_0 . A *type II error* occurs when the alternative hypothesis is true, but we do not reject the null hypothesis (because the p-value was too large). Type I and type II errors are in opposition to one another. For a given type of p-value, we can lower the type I error rate only by raising the type II error rate. Using a p-value threshold of 0.01 will lead to less type I errors, but more type II errors, than using a p-value threshold of 0.05.

A rejection of the null hypothesis should not lead to unscrutinized acceptance of the alternative hypothesis. The alternative hypothesis may also be a poor description of the data, perhaps even more so. Similarly, a failure to reject the null hypothesis does not mean that the null hypothesis is a better description of the data than the alternative. It simply means that the statistical evidence is insufficient to rule out the null hypothesis (for the type I error rates that we are willing to tolerate).

A full discussion of p-values and their connections to other common concepts in hypothesis testing, such as power, critical region, size, and level, is beyond the scope of this entry. Any introductory statistics textbook is likely to have a thorough exposition of these and other hypothesis testing concepts. Casella and Berger (2002) is an intermediate-level reference. Lehmann and Romano (2005) is an advanced, comprehensive source. Kass et al. (2014) is an accessible reference aimed for the neuroscience community.

Construction of p-Values

Here, we will focus on a special type of p-value that is particularly relevant for resampling methods in neurostatistics. Let T be any function of the data and let P be a special probability distribution for the data, both of which will be discussed later. Here, T is called the *test statistic* and P is called the *null distribution*. For any potential data set x , define.

$$p(x) = \text{Prob}(T(Y) \geq T(x)) \text{ when } Y \text{ has distribution } P. \quad (2)$$

In words, $p(x)$ gives the probability that a random data set Y would have a test statistic T at least as large as x has, if Y was chosen according to the null distribution P . (When computing the probability, only Y is random; x is held fixed. See section “[Heuristic Resampling](#)” for additional intuition.) In certain special cases, using Eq. 2 to define $p(X)$ creates a p-value, meaning that it satisfies property (1) for an appropriate null hypothesis. For instance, if the null hypothesis is simply that the data have distribution P , then $p(X)$ is a p-value for this null hypothesis. In many cases, p-values cannot be created using Eq. 2, but a discussion of these cases is beyond the scope of this entry.

Example 1

Let $X = (X_1, \dots, X_n)$ be a sequence of n independent coin flips with common probability θ of heads. Let $T = \# \text{heads}$. Let P correspond to the case $\theta = 0.5$ and let the null hypothesis be the same, namely, $H_0: \theta = 0.5$. Using Eq. 2 in this case gives

$$\begin{aligned} p(x) &= \text{Prob}(T(Y) \geq T(x)) \\ &= \sum_{k=T(x)}^n \text{Prob}(T(Y) = k) \\ &= \sum_{k=T(x)}^n \binom{n}{k} 0.5^n, \end{aligned}$$

where $\binom{n}{k} = n!/(k!(n-k)!)$ is the number of distinct ways to have k heads in a sequence of n coin flips and where the computation is done for Y having probability distribution P . Then $p(X)$ is a p-value for H_0 . (To compute $p(X)$, we substitute the observed value of X for the variable x on the right side of the derived formula for $p(x)$ above.) If we observe 7 heads in 10 flips, then the p-value is 0.172. If we had decided to reject H_0 when the p-value was less than 0.2, then we would reject. If instead we had chosen a threshold of 0.1, then we would not reject. This p-value is designed to be used when we anticipate that the coin might favor heads in cases where the null is false. For example, if we observe 3 heads in 10 flips, then the p-value is 0.945 and we would normally not reject, even though there is a sense in which 3 heads and 7 heads are equally extreme observations for a fair coin. By changing the test statistic, T , we could create a p-value that was more symmetric in its behavior or one that tended to be small for large numbers of tails. The choice depends on the scientific context and on the desired error performance. Finally, we note that the original p-value is also a p-value for the null hypothesis $H_0: \theta \leq 0.5$, illustrating that this method of constructing p-values based on a single null distribution P can sometimes be used even when the null hypothesis includes many distributions.

This method in Eq. 2 of constructing a p-value based on a test statistic T and a null distribution P maps closely onto what is normally done with resampling methods in neuroscience. Within this context, there are several important issues:

- Choice of the null hypothesis H_0
- Choice of the null distribution P
- Choice of the test statistic T
- Computation of the p-value $p(X)$
- Adjustments for multiple hypothesis tests.

We will discuss each of these in the remainder of this entry.

Choice of H_0 and P

The choice of the null hypothesis, including the choice of the underlying statistical model, is arguably the most important choice among the items listed in the previous paragraph. The null hypothesis needs to be appropriate for the scientific question and the available data. Despite its centrality, there is little to say here about H_0 , because it is so context dependent. Perhaps the best guidance is to *always clearly state the complete statistical model and the null hypothesis*. Only when H_0 is clearly stated can one interpret the conclusion of a hypothesis test and judge its scientific relevance.

Given H_0 , the next step is to choose a null distribution P under which a p-value can be computed. If H_0 is a *simple null hypothesis*, meaning that it consists of a single hypothesized probability distribution for the data, then we can take P to be this unique distribution specified by H_0 . If H_0 is a *composite null hypothesis*, meaning that it consists of many possible probability distributions for the data, then it may be difficult to find an appropriate P or one may not even exist. Example 1 above illustrates both a simple null hypothesis ($H_0: \theta = 0.5$) and a composite null hypothesis ($H_0: \theta \leq 0.5$) and a corresponding null distribution P (which happens to be the same for each, in this case).

Example 2

Let $X' = (X'_1, \dots, X'_n)$ be a sequence of n independent coin flips with a fixed, but unknown, common probability v' of heads. Let $X'' = (X''_1, \dots, X''_n)$ be another sequence of n independent coin flips with a fixed, but unknown, common probability v'' of heads. In this case, the data are $X = (X', X'')$. The null hypothesis H_0 is that X' and X'' are independent. H_0 is a composite null hypothesis because v' and v'' are not specified by H_0 and are unknown. The unknown parameters $v = (v', v'')$ are often called *nuisance parameters*, because they are necessary to specify the probability distribution but are otherwise unrelated to the target

statistical question – in this case, a question about independence.

Let $T = T(X) = \#\{i: X'_i = X''_i = \text{heads}\} = \#$ aligned heads, which we might expect to be large if X' and X'' are positively correlated. The distribution of T depends heavily on the unknown parameters v and is not uniquely specified if these parameters are not known. Hence, a null distribution P for computing p-values is not apparent. For example, T could be large because the sequences are correlated or because v' and v'' are both large, resulting in many heads, some of which are likely to align by chance. Bootstrap approximation and conditional inference are two common approaches for specifying a null distribution P in situations like this with nuisance parameters. Each is considered below in the continuation of this example.

This example is stereotypical of early frameworks for testing for synchronization between two simultaneously recorded neural spike trains, modeled by X' and X'' , with heads denoting a spike (an action potential) in a small time bin and tails denoting no-spike. The unknown parameters v' and v'' are often called the theoretical firing rates of the respective neurons, and $N(X')$ and $N(X'')$ correspond to the observed spike counts, where $N = \#$ heads. T is the number of precisely synchronous spikes. This simple framework is no longer thought to be appropriate, particularly when recording *in vivo*, because, among other things, the underlying modeling assumption that v' and v'' are constant in time is usually a very poor description of the data. More recent approaches improve on this simple framework both by mak-

ing the underlying modeling assumptions more believable and by aligning the null hypotheses more closely with the scientific questions of interest (Amarasingham et al. 2012; Harrison et al. 2013, ► “Surrogate Data for Evaluation of Spike Correlation” in this encyclopedia).

Bootstrap Approximation

Consider a composite null hypothesis H_0 that would admit a null distribution if we happened to know the value of some nuisance parameter v . The null distribution might be different for each v , say $P = P_v$, which, using Eq. 2, would give rise to a different p-value for each v , say $p(X) = p_v(X)$. One possibility is to use the observed data to obtain an estimate $\hat{v}$ for v and then use the approximate p-value $p_{\hat{v}}(X)$ in place of the true p-value $p_v(X)$. It is an approximate p-value, because the true unknown value of v is replaced with an approximation $\hat{v}$ estimated from data. Usually, Eq. 1 will not hold exactly for an approximate p-value.

Example 2 Part II: Bootstrap Approximation

Continuing Example 2, suppose for the moment that we happen to know the true values of v' and v'' . Then the null hypothesis becomes a simple null hypothesis, namely, that X' and X'' are sequences of independent coin flips with probability of heads given by the known values of v' and v'' , respectively. Using Eq. 2 gives

$$\begin{aligned} p_v(x) &= p(x) = \text{Prob}(T(Y) \geq T(X)) \\ &= \sum_{i=0}^n \sum_{j=0}^n \sum_{k=T(x)}^n \text{Prob}(N(Y') = i, N(Y'') = j, T(Y) = k) \\ &= \sum_{i=0}^n \sum_{j=0}^n \sum_{k=T(x)}^n \binom{n}{i} \binom{n}{j} \binom{n-i}{j-k} (v')^i (1-v')^{n-i} (v'')^j (1-v'')^{n-j}, \end{aligned} \quad (3)$$

where $x = (x', x'')$, where $N = \#$ heads, where we take $\binom{a}{b} = 0$ if $a < b$ or $b < 0$, and where

the computation is done for $Y = (Y', Y'')$ satisfying the null hypothesis for parameters $v = (v', v'')$. The

specific formula for this p-value is not the main point. The key observation is that we could compute $p(X)$, at least in principle, if we knew the values of the test statistic $T = T(X)$ and the parameters v . For instance, if $n = 10$, $v' = 0.3$, $v'' = 0.5$, and we observe $T = 5$, then the p-value is 0.0099. Note that we have emphasized this dependence on the parameters by writing

$$p(x) = p_v(x).$$

But what if v' and v'' are unknown, as originally stipulated in Example 2? One possibility is to estimate their values from the observed data, pretend that their estimated values are correct, and then use the p-value derived above for the case where the parameters are known. If $\hat{v} = (\hat{v}', \hat{v}'')$ are the estimated values, then we would use the approximate p-value

$$p_{\hat{v}}(X)$$

as given by Eq. 3. For instance, if $n = 10$ and we observe $N(X') = 5$ and $N(X'') = 6$, then we might estimate $\hat{v}' = 0.5$ and $\hat{v}'' = 0.6$ (these are the maximum likelihood estimates). If we additionally observe $T = 5$, then the approximate p-value is 0.1503. It is only an approximate p-value, because the true v' and v'' are replaced by estimates from the data. As n gets large, the approximation will improve and the approximate p-value will come closer and closer to being a true p-value in the sense of Eq. 1.

The substitution of the unknown nuisance parameters with their estimates from the data is sometimes called the *substitution method* (or *substitution principle*). Here we use the term *bootstrap approximation*, because it is the first and most important step in bootstrap and because this type of substitution arises almost exclusively in connection with bootstrap in resampling methods for neuroscience. Bootstrap approximations are easy to use and easy to misuse. In Example 2 part II above, the null hypothesis only had two nuisance parameters that needed to be estimated from the data. A more modern example from neuroscience

might have hundreds or thousands or even infinitely many nuisance parameters. Estimating a large number of parameters from data is fraught with difficulty and the estimation errors are essentially guaranteed to be large in some respects. For bootstrap approximations to work well in these situations, the p-value itself must be fairly insensitive to certain types of large approximation errors. Even in cases with only a single nuisance parameter, bootstrap approximations can fail (meaning that they perform poorly no matter how much data is available), usually in cases where the p-value in Eq. 2 is unusually sensitive to tiny changes in the nuisance parameter. There is a substantial literature about both the theoretical properties of bootstrap approximations and their practical use (Davison and Hinkley 1997).

Conditional Inference

Consider a composite null hypothesis H_0 that would admit a null distribution if we happened to condition on the value c of some statistic C , which we call a *conditioning statistic* (and is different from the test statistic). The null distribution might be different for different values of c , say $P = P^c$, which, using Eq. 2, would give rise to a different p-value for each c , say $p(X) = p^c(X)$. Since we can directly observe $c = C(X)$, however, this causes no difficulties, and $p^{C(X)}(X)$ is a valid p-value for the null hypothesis. The most common situation where we can use conditioning to create a null distribution is when $\text{Prob}(X = x | C(X) = c)$ is the same function of x and c regardless of the specific distribution of X , as long as X satisfies the null hypothesis. In this case, we can take $P^c(x) = \text{Prob}(X = x | C(X) = c)$.

Example 2 Part III: Conditional Inference

Continuing Example 2, if we use the conditioning statistic $C(X) = (N(X'), N(X''))$, which is the total number of heads for each of the two coins and assume the null hypothesis is true, then the conditional distribution of the data given the conditioning statistic is.

$$\begin{aligned}
& \text{Prob}(X = x | C(X) = c) \\
&= \frac{\text{Prob}(X' = x', X'' = x'', N(X') = c', N(X'') = c'')}{\text{Prob}(N(X') = c', N(X'') = c'')} \\
&= \frac{\left[\prod_{i=1}^n (v')^{x'_i} (1 - v')^{1-x'_i} (v'')^{x''_i} (1 - v'')^{1-x''_i} \right] I(N(X') = c') I(N(X'') = c'')}{\binom{n}{c'} (v')^{c'} (1 - v')^{n-c'} \binom{n}{c''} (v'')^{c''} (1 - v'')^{n-c''}} \\
&= \frac{I(N(X') = c') I(N(X'') = c'')}{\binom{n}{c'} \binom{n}{c''}},
\end{aligned} \tag{4}$$

where $x = (x, x')$, where $c = (c, c')$, and where I denotes the indicator function having $I(A) = 1$ if A is true and $I(A) = 0$ if A is false. In words, it says that if the two coins are independent, then the conditional distribution of the arrangement of heads and tails, given the number of heads for each coin, does not depend on the unknown probability of heads for each coin. Furthermore, the common conditional distribution is *uniform* meaning that all possible arrangements of heads and tails are equally likely, subject to having the correct numbers of heads. Since this conditional distribution does not depend on the unknown nuisance parameters v' and v'' , we can use it as a null distribution for the null hypothesis of independence, namely,

$$\begin{aligned}
P(x) &= P^c(x) \\
&= \frac{I(N(X') = c') I(N(X'') = c'')}{\binom{n}{c'} \binom{n}{c''}}.
\end{aligned} \tag{5}$$

The (conditional) null distribution in Eq. 5 does not depend on the unknown parameters v' and v'' , but it does depend on the observed number of heads c' and c'' . This presents no difficulties, though, since we can directly observe these values from data. Using the test statistic $T = \# \text{aligned heads}$ as before and using Eq. 2 to compute the p-value give

$$\begin{aligned}
p^c(x) &= \sum_{k=T(x)}^n \text{Prob}(T(Y) = k) \\
&= \sum_{k=T(x)}^n \frac{\binom{n}{c'} \binom{c'}{k} \binom{n-c'}{c''-k}}{\binom{n}{c'} \binom{n}{c''}},
\end{aligned} \tag{6}$$

where we take $\binom{a}{b} = 0$ if $a < b$ or $b < 0$ and where $Y = (Y', Y'')$ has the joint pmf P^c given in Eq. 5. Again, the specific form of the p-value is not the main point. We can observe $c = (c', c'') = (N(X'), N(X''))$ and, at least in principle, compute the valid p-value $p^c(X)$. For instance, if $n = 10$ and we observe $N(X') = 5$, $N(X'') = 6$ and $T(X) = 5$, then the p-value is 0.0238.

Conditional inference creates a null distribution without needing to use a bootstrap approximation. This can be an advantage in settings with many nuisance parameters, where the bootstrap approximation may be poor. Conditional inference can also be robust to modeling assumptions about the conditioning statistic, C , which is desirable in many contexts. Conditional inference is more limited than bootstrap approximation, however, since many examples do not have an appropriate conditioning statistic, C . The two approaches can also be combined if conditioning still leaves some unknown parameters that need to be estimated.

It is important to note that bootstrap approximation and conditional inference usually lead to

different types of p-values. For example, the same data at the ends of Example 2 parts II and III gives an approximate p-value of 0.1503 using a bootstrap approximation and a p-value of 0.0238 using conditional inference. The difference between the two is not a result of approximation errors from the bootstrap approximation. Rather, the two methods lead to fundamentally different types of p-values. Both control the type-I error rate in the usual way (only approximately so for bootstrap), but each will have different type-II error profiles. One is not necessarily better than the other. The bootstrap approximate p-value is larger in this case because it accounts for the fact that T could be large by seeing an unusually large number of heads, whereas conditional inference uses knowledge about the observed number of heads and notes that T is unusually large (in fact, it is as large as possible) given the number of heads. The scientific context will dictate which of these is preferable.

Heuristic Resampling

The intuition behind the p-value in Eq. 2 is straightforward. If we repeatedly generate surrogate data sets Y according to some probability distribution P and see what fraction of them gives test statistics that are at least as extreme as the original data (if we did this infinitely many times, then the fraction would match the p-value formula), then we can gauge how unusual the original data are with respect to P . There are many examples in the literature where this intuition is implemented directly with some choice of P that makes intuitive sense, but that has not been derived directly from a well-formulated null hypothesis. These heuristic procedures can lead to revealing exploratory analyses, but the “p-values” obtained from them are rarely valid p-values for any null hypothesis. A “rejection” is particularly difficult to interpret, since there is no clear null hypothesis that is being rejected and since the numerical value of the “p-value” cannot be interpreted in the usual manner in terms of type-I error rates. Whenever possible, it is preferable to develop a proper null hypothesis and communicate the results with a valid p-value.

Choice of T and the Alternative Hypothesis

Much like the choice of H_0 , the choice of T is critical but also highly problem-dependent. The choice of T is closely related to the concept of an alternative hypothesis. In most cases, investigators not only formulate a null hypothesis, but they also have rough expectations about how the data will appear if the null hypothesis is false. For example, when testing the null hypothesis of independence between two spike trains, in some settings, one might expect that a lack of independence will manifest itself as an abundance of synchronous spiking at some time scale. Usually T is chosen to capture this anticipated departure from the null behavior. The more precisely the alternative hypothesis is formulated, the more precisely T can be tailored to detect differences between the null and alternative hypotheses in the data.

Perhaps the most important guidance is *to avoid unscrutinized acceptance of the alternative hypothesis* after rejecting the null hypothesis. Usually, the alternative hypothesis is only one of many ways for the null hypothesis to be wrong. Careful choice of T can help ensure that the alternative hypothesis is detected, if it happens to be true, but for any choice of T , there are often many other distributions (not in the null or alternative hypotheses) that are also well detected. For example, suppose we reject the null hypothesis of independence between two spike trains using a test statistic that involves precise (millisecond-precision) synchronous spiking. While it is true that we can conclude that the neurons are dependent (this is the rejection of the null hypothesis), we should be careful not to immediately assume the existence of processes that create fine-precision spike timing (which would be acceptance of some specific alternative hypothesis that we have in mind, usually the one that motivated our choice of test statistic). There are many ways to be dependent that may create excess amounts of precise synchrony without involving precise spike timing.

Another important point is that *changing T changes the p -value and its properties*. Consequently, T cannot be chosen after inspecting the data or the resulting p -value will not be valid (cf., Kriegeskorte et al. 2009). Simple choices of T are easier to interpret and also less likely to raise concerns that T was tailored to the data.

Multiple Hypothesis Tests

Many experiments lead to multiple hypothesis tests. These could be different null hypotheses and/or different p -values for the same null hypothesis but tailored to different alternative hypotheses (typically created by using different test statistics). For example, when testing for differences between experimental conditions, there may be different hypothesis tests for each of many different spike trains, or different brain regions, or different time intervals. There are two key issues to keep in mind when performing multiple hypothesis tests.

First, *the pattern of accepted and rejected hypotheses may not correspond to the underlying pattern of true and false null hypotheses*. There are many influences on the *power* of a test to detect violations of the null hypothesis, including the amount and quality of the data, the strength of the signal, the appropriateness of the test statistic, and so on. The pattern of rejections may reflect underlying fluctuations in power resulting from processes that are scientifically unrelated to those which are being studied by the hypothesis tests. For example, rejecting a null hypothesis of independence between spike trains in one experimental condition, but not another, is not necessarily strong evidence that the dependence structure has changed across conditions. Perhaps the firing rates changed across conditions and this influenced the power of the hypothesis test to detect dependence?

Second, *large numbers of hypothesis tests will lead to some false rejections unless p -values are adjusted for multiple tests*. For example, suppose that we simultaneously record spike trains from 100 neurons in each of two experimental conditions and then, for each neuron separately, construct a p -value to test whether the neuron's

response distribution differed across conditions. If we reject the null hypothesis of no difference across conditions whenever a p -value is less than 0.05, then (assuming the p -values are not overly conservative) we can expect roughly 5 rejections even if all 100 null hypotheses are true. If, further, the p -values are not overly correlated, then the probability of at least one false rejection among these 100 tests is close to one. The basic interpretation of a p -value has apparently been diluted by performing multiple hypothesis tests.

There is a vast and active literature about methods for adjusting p -values so that they maintain various interpretations in the presence of multiple tests (Farcomeni 2008; Nichols and Hayasaka 2003). A common approach is to adjust p -values so that they control the *family-wise error rate (FWER)*, which is the probability of one or more false rejections among all hypothesis tests in the family (regardless of the actual pattern of true and false null hypotheses). Defining this formally requires some care. Let $H_0^{(1)}, \dots, H_0^{(h)}$ be the collection of h null hypotheses and let $V \subseteq \{1, \dots, h\}$ denote the (unknown) indices of the true null hypotheses. We say that $p^{(1)}(X), \dots, p^{(h)}(X)$ are FWER-adjusted p -values for these null hypotheses if

$$\begin{aligned} \text{Prob}\left(p^{(k)}(X) \leq \alpha \text{ for one or more } k \in V\right) \\ \leq \alpha \text{ for all } 0 \leq \alpha \leq 1, \end{aligned}$$

for every possible distribution of X . Now, if we only reject those null hypotheses where the adjusted p -values are 0.05 or less, then our probability of falsely rejecting even a single true null hypothesis is at most 0.05. The Bonferroni correction is the simplest method to create FWER-adjusted p -values. Beginning with a collection of p -values, $p^{(1)}, \dots, p^{(h)}$, we simply multiply the original p -values by the number of tests, h , to get the adjusted p -values, i.e.,

$$p^{(k)}(x) = hp^{(k)}(x) \quad (k = 1, \dots, h)$$

Although the Bonferroni correction appropriately controls the type-I error rates (in the sense of FWER), it can have poor type-II error rate

performance. In particular, if the number of tests is large, then unadjusted p-values must be very small in order to reject using the Bonferroni-adjusted p-values. There exist improvements to the Bonferroni correction that provide the same FWER guarantees.

For situations with very large numbers of tests, controlling the FWER may be a too stringent goal, and statisticians have defined a variety of more relaxed criteria. For example, the *false discovery rate* (FDR) is the expected proportion of rejections that are false rejections (defining the proportion to be zero if there are no rejections), and methods that control the FDR bound this expected proportion. Loosely speaking, controlling the FDR allows there to be some false rejections, but hopefully not too many. Like the Bonferroni procedure for FWER, there are simple procedures for controlling the FDR, such as the Benjamini-Hochberg-Yekutieli correction, that require only a collection of unadjusted p-values.

Procedures for adjusting for multiple hypothesis tests require the original, uncorrected p-values to be actual *valid* p-values in the sense of Eq. 1. Using multiple testing adjustments on approximate p-values (such as approximate p-values resulting from bootstrap or from asymptotic approximations) requires great care. Multiple testing adjustments tend to amplify approximation errors, and errors that are insignificant for single hypothesis tests can easily corrupt multiple testing interpretations. For example, uncorrected p-values of 10^{-5} and 10^{-10} are essentially equivalent if we are testing a single null hypothesis at level 0.05, and a procedure that could approximate p-values to within 10^{-5} would be more than adequate for most purposes. But if this is one of a million different p-values, then 10^{-5} and 10^{-10} are quite different – only the latter would be unusual to see somewhere among the million p-values (consider a Bonferroni correction with $h = 10^6$) – and even tiny approximation errors could drastically alter our final conclusions.

Monte Carlo Approximation of p-Values

The examples above are special in that the p-values have a simple closed-form expression

that is easy to compute. In many practical settings, there may be no practical methods for exactly computing the p-value in Eq. 2: $p(x) = \text{Prob}(T(Y) \geq T(x))$ when Y has distribution P . It is easy to approximate the p-value, however, as long as we can sample from the null distribution P . Loosely speaking, if we generate many random observations from P , then the p-value is closely approximated by the fraction of those observations that have test statistics at least as large as the original data. This is called *Monte Carlo* approximation. Furthermore, we can engineer our Monte Carlo p-value to actually be a valid p-value in sense of Eq. 1. As mentioned in section “Multiple Hypothesis Test”, using valid p-values is especially important in the context of multiple hypothesis testing.

Let $Y^{(1)}, \dots, Y^{(m)}$ be a random sample from the null distribution P . (Using superscripts to index the observations in the Monte Carlo sample will be convenient later.) The Monte Carlo p-value is

$$\begin{aligned} \hat{p}(x) &= \hat{p}(x; Y^{(1)}, \dots, Y^{(m)}) \\ &= \frac{\#\{k : T(Y^{(k)}) \geq T(x)\} + 1}{m + 1}. \end{aligned} \quad (7)$$

Without the 1 in the numerator and denominator, this is simply the fraction of the $Y^{(k)}$'s with $T(Y^{(k)}) \geq T(x)$. Including the 1 is like including a copy of x among the $Y^{(k)}$'s when computing this fraction, and it ensures that $\hat{p}(X; Y^{(1)}, \dots, Y^{(m)})$ is a valid p-value for the original null hypothesis. Validity means that the type I error is controlled appropriately. As the Monte Carlo sample size, m , gets large, $\hat{p}(X)$ will be a better and better approximation of the target p-value, $p(X)$. Consequently, for large m , both p and $\hat{p}$ control the type II error in similar ways.

Example 2 Part IV: Monte Carlo p-Values

Revisiting Example 2, look again at the bootstrap approximate p-value formula in Eq. 3 and the conditional inference p-value formula in Eq. 6. What if these formulas were not available or too difficult to compute? Monte Carlo approximation is often a good alternative.

Consider first the bootstrap approximation from Example 2 part II. We first estimate the unknown nuisance parameters from the observed data using $\hat{v} = (\hat{v}', \hat{v}'')$, and we hold these parameters fixed throughout the rest of the procedure. Now, we artificially generate a random data set that satisfies the null hypothesis using the parameters $\hat{v}$. There is no ambiguity about which distribution to use for the random data set, because once the nuisance parameters are specified, the null hypothesis contains only a single distribution $P = P_{\hat{v}}$. For this example, to generate a random data set $Y = (Y', Y'')$, we first sample $Y' = (Y_1', \dots, Y_n')$ independently from a coin with probability of heads $\hat{v}'$. Then, independently from Y' , we sample $Y'' = (Y_1'', \dots, Y_n'')$ independently from a coin with probability of heads $\hat{v}''$. $Y = (Y', Y'')$ is a single random data set from the (bootstrap approximate) null distribution P . Let us call this data set $Y^{(1)}$. Now, using the same $\hat{v}$, we independently repeat this procedure many times to get a collection of Monte Carlo data sets $Y^{(1)}, \dots, Y^{(m)}$, which is a random sample of size m from the (bootstrap approximate) null distribution $P = P_{\hat{v}}$. We can compare the observed number of aligned heads $T(X)$ to the collection of numbers of aligned heads from the Monte Carlo data $T(Y^{(1)}), \dots, T(Y^{(m)})$ to get a Monte p-value $\hat{p}(X)$, as defined in Eq. 7. For large m , $\hat{p}(X) \approx p_{\hat{v}}(X)$ from Eq. 3 (with v replaced by $\hat{v}$). Note that $\hat{p}(X)$ would itself be a valid p-value if the Monte Carlo sample came from P_v , but it does not. It comes from $P_{\hat{v}}$ which, if our bootstrap approximation is good, will be very close to P_v . The combination of a bootstrap approximation and Monte Carlo approximation is called **bootstrap**, and in this case, it would be called *parametric bootstrap hypothesis testing* – parametric, because our bootstrap approximation involves the estimation of a fixed and finite number of parameters (in this case, two parameters: v' , v''). It is important to remember that the bootstrap approximation is the key approximation in bootstrap. Monte Carlo approximation is only done for computational convenience, and usually m can be chosen sufficiently large that the Monte Carlo approximation error is negligible.

Now consider conditional inference from Example 2 part III. We first observe the numbers of heads $c = C(X) = (N(X'), N(X'')) = (c', c'')$ coming from the two coins in the original data, and we define the null conditional distribution $P = P^c$ as in Eq. 5. To generate a random data set $Y = (Y', Y'')$ from P , we first generate $Y' = (Y_1', \dots, Y_n')$ by choosing c' of flips to be heads, $n - c'$ of the flips to be tails, and uniformly shuffling the order, so that each of the $\binom{n}{c'}$ possibilities is equally likely. Another way of thinking about this is to randomly and uniformly shuffle the order of the flips in the original sequence X' , which automatically has c' heads. Then we independently do the same thing for $Y'' = (Y_1'', \dots, Y_n'')$, but using c'' heads and $n - c''$ tails. Calling this shuffled data set $Y^{(1)} = Y$, we can repeat this process independently, each time using the same $c = (c', c'')$, to get a Monte Carlo random sample $Y^{(1)}, \dots, Y^{(m)}$ from the null conditional distribution P . Exactly like the bootstrap sample, we compute $\hat{p}(X)$ using Eq. 7. For large m , $\hat{p}(X) \approx p^c(X)$. Furthermore, $\hat{p}(X)$ is itself a valid p-value.

Example 3: Permutation Tests

Let S_k denote the spike train data collected on trial k and let $E_k \in \{1, 2\}$ denote which of two experimental conditions was in effect during trial k . The complete data set of n trials (each of the same duration) is $X = (S, E)$, where $S = (S_1, \dots, S_n)$ and $E = (E_1, \dots, E_n)$. We assume that $E_1, \dots, E_n$ are *exchangeable*, which means that every possible ordering of experimental conditions was, in principle, equally likely to occur. (Usually, this is easy to ensure as part of the overall experimental design.) We want to test whether the experimental condition is related to the spiking data. The formal null hypothesis is that S and E are independent, that is, the experimental condition has no effect on spiking. We conjecture that if the null hypothesis is false (i.e., if there is a difference across conditions), then it will be reflected in the distribution of total spike counts over a trial, namely, $N(S_k) = \#$ spikes in $S_k = \#$ spikes on trial k . In particular, we

expect the average spike count in condition 1 to be different from the average spike count in condition 2, quantified by the absolute difference:

$$T(X) = T(S, E) = \left| \frac{\sum_{k:E_k=1} N(S_k)}{\#\{k : E_k = 1\}} - \frac{\sum_{k:E_k=2} N(S_k)}{\#\{k : E_k = 2\}} \right|.$$

This will be our test statistic.

The null hypothesis of independence is a very large composite null hypothesis. Without further assumptions, there are infinitely many nuisance parameters needed to specify the distribution of S . We will use conditional inference to specify a unique null distribution P . Let $D = D(E) = \#\{k: E_k = 1\}$ be the number of trials in experimental condition 1. Our conditioning statistic will be $C = C(X) = (S, D)$, that is, we will condition on all of the spike train data, including the order of the trials, and we will also condition on the number of trials in experimental condition 1 (and, consequently, the number of trials in experimental condition 2, which is $n - D$). The only uncertainty remaining is the ordering of E , that is, the pairing of experimental condition with trial. Under the null hypothesis of independence (and assuming E was constructed to be exchangeable), then every possible ordering of E is equally likely. The null conditional distribution is just the uniform distribution over all possible $\binom{n}{D}$ pairings of trials with condition labels. Since this conditional distribution is the same for all possible distributions in the null hypothesis, we can use it as our null distribution without needing to estimate any nuisance parameters or to introduce additional modeling assumptions. To sample from this distribution, we simply shuffle, or permute, the experimental condition labels relative to the trials. We can do this many times, each time computing the test statistic T . (Note that T will change because we are changing which trials are assigned to the different experimental conditions.) Equation 7 gives a valid Monte Carlo p-value for this hypothesis test, which is called a Monte Carlo *permutation test*.

Example 4: Trial Shuffling

This is similar to Example 3, except that now E_k is spike train data from another neuron recorded simultaneously with S_k . The null hypothesis is still independence – in this case, independence between neurons. We change the test statistic to be the absolute correlation coefficient (Pearson's r) between spike counts:

$$T(X) = T(S, E) = |\text{corr} - \text{coef}((N(S_k), N(E_k)) : k = 1, \dots, n)|.$$

To create a unique null distribution, we condition on all of S , as before, and we condition on all of E except for the specific order of the trials in E . The null hypothesis of independence, combined with the assumption that E is exchangeable, gives the uniform conditional null distribution over the ordering of the trials for E . To sample from this null distribution, we simply shuffle the order of E 's trials. Monte Carlo p-values are computed in the usual way.

Scientifically, interpreting a rejected null hypothesis in this case requires some care. For instance, unlike Example 3, where we could design E to be exchangeable, here we must assume that E is exchangeable. In some experiments, this may not be true. For example, if the neurons are modifying their response functions over trials (because of, say, habituation or learning or fatigue or metabolic changes), then trials are not exchangeable. When this modification affects both neurons, then it may be detectable using the correlation coefficient test statistic. It likely depends on the experimental context whether this type of co-modulation reflects the underlying mechanisms the investigator was intending to detect with a test of independence. This final caution holds more generally. There are many mechanisms, including experimental artifacts, such as misaligned trials, that can create dependence between spike trains. With sufficient data and an appropriate test statistic, trial shuffling can detect these dependencies, but it cannot determine which mechanisms created the dependencies.

Summary

The perspective of this entry is that spike train resampling is best viewed as Monte Carlo hypothesis testing. More specifically, the procedure of using surrogate data created by resampling spike trains for the purpose of evaluating the significance of patterns observed in the data is best viewed as Monte Carlo sampling from a null hypothesis that admits a unique null distribution for the purpose of numerically approximating a p-value. The key concepts underlying this view are reviewed above, along with some standard guidance about the use and misuse of hypothesis testing. The entry ► [“Surrogate Data for Evaluation of Spike Correlation”](#) in this encyclopedia describes many of the commonly used methods for resampling spike trains.

Simulation Experiment Description Markup Language (SED-ML)

Dagmar Waltemath¹ and Nicolas Le Novère^{2,3}

¹Systems Biology and Bioinformatics, University of Rostock, Rostock, Germany

²Babraham Institute, Babraham Research Campus, Cambridge, UK

³EMBL European Bioinformatics Institute, Cambridge, UK

Definition

The Simulation Experiment Description Markup Language is an XML-based exchange format for

the encoding of simulation experiments mainly in the field of computational biology. It stores the simulation recipe, including the models used in the experiment, the pre- and post-processing procedures, and the instructions for how to generate the simulation output.

Detailed Description

Overview

The Simulation Experiment Description Markup Language (SED-ML) encodes simulation setups in XML. Thereby it provides a means to exchange simulation descriptions in standard format. SED-ML respects the Minimum Information Guidelines for Simulation Experiments (Minimum Information About a Simulation Experiment, MIASE (Waltemath et al. 2011a)). Following these recommendations, the first version of SED-ML has been published in March 2011 (Waltemath et al. 2011b). It covers the description of time-course simulations and consists of five major building blocks:

1. The **Model** entity contains references to the models used in the simulation experiment and pre-processing procedures on these models before simulation. Models must be in standard representation formats (e.g., SBML, CellML, NeuroML). Examples for pre-processing are, e.g., changing the value of an observable, computing the change of a value using mathematics, or general changes on any XML element of the model representation.
2. The **Simulation** entity contains all information about the simulation settings and the steps taken during simulation, e.g., the particular type of simulation and the algorithm used for the execution of the simulation.
3. The **Task** entity applies one of the defined simulations on one of the referenced models at a time.
4. The **DataGenerator** entity encodes post-processing procedures which need to be

applied to the simulation result before output, e.g., normalization of data.

5. The **Output** entity specifies the simulation output, e.g., the particular plots to be shown.

Structure of SED-ML

Model Elements

The SED-ML model elements define the identity and location of the model(s) to be simulated and specify the model's native encoding format. The location is to be given as a Uniform Resource Identifier (URI), which enables software interpreting SED-ML to retrieve the model. In case of a relative URI, the base is the location of the referring SED-ML file. The SED-ML archive format can furthermore be used to share model and simulation descriptions together (see the specification (Waltemath et al. 2011b)). In addition to defining the source model's location and encoding, SED-ML model elements can also list changes to be applied to a model before simulation. Such changes could be altering attribute values (e.g., a parameter value in an SBML model or the `initial_value` of a CellML variable) or changing the model structure. Attribute values may undergo a simple substitution or more complex calculation using content MathML 2.0 (<http://www.w3.org/Math/>). The model structure may be changed by adding or removing XML elements.

Simulation Elements

The SED-ML simulation elements define the simulation algorithms to be used in the experiment and their configuration. Simulation algorithms are specified using terms from the Kinetic Simulation Algorithm Ontology (KiSAO, <http://biomodels.net/kisao/>). KiSAO classifies and characterizes kinetic simulation algorithms. Furthermore, configuration details of the simulation can be described in SED-ML, such as the start and end times or the number of time points to output. The current implementation supports the description of time-course simulation setups. Extensions towards further experiment types are already being discussed and will be available

in the next versions, including the description of steady-state analyses and nested simulations, such as parameter scans.

Task Elements

The SED-ML task elements apply a particular simulation algorithm to a specific model. Because simulations and models are described independently, they can be combined in diverse ways. Tasks allow for this flexibility. For example, a simulation can be applied to different versions of a model with varying parameterization.

DataGenerator Elements

The SED-ML dataGenerators define transformations of raw simulation output (as generated by a task) into the desired numerical form. They can simply be references to a model variable but may also be defined through complex mathematical expressions encoded using content MathML. Some variables used in an experiment are not explicitly defined in the model, but may be implicitly contained and can be addressed using SED-ML-specific constructs. The SED-ML website provides a mapping of these SED-ML symbols onto possibly existing concepts in the individual languages.

Output Elements

The SED-ML output elements describe how numerical data from the data generators are grouped together. SED-ML allows to generate 2D and 3D plots or sets of unrelated arrays.

SED-ML Development

SED-ML is a community-driven project that is part of the COmputational Modeling in Biology NEtwork (COMBINE, <http://co.mbine.org>). SED-ML development is coordinated by five elected editors. Format extensions are discussed on the SED-ML mailing list and on annual meetings. Simulation descriptions in SED-ML are currently provided for SBML and CellML models.

The adoption of SED-ML for NeuroML models is ongoing.

Software Support

SED-ML files can be created and read using software libraries and tools (Waltemath et al. 2011c). The libSedML (<http://libsedml.sf.net/>) is a set of .NET libraries for reading, validating, and writing SED-ML descriptions, along with all necessary utility functions for resolving models and XPath expressions. The libSedMLScript, which is part of libSedML, provides a script-based language for defining SED-ML experiments. Alternatively, jlibsedml (<http://sourceforge.net/projects/jlibsedml/>) is a Java library for creating, manipulating, validating, and working with SED-ML documents. The jlibsedml application programming interface (API) follows a similar organization to that of libSBML, a successful and popular library for manipulation of SBML documents. SProS (the SED-ML Processing Service) is an API for creating, reading, and manipulating SED-ML documents. It is integrated in the CellML API. Future versions of SProS will also provide support for running simulations described in SED-ML and involving CellML models (using the simulation facilities already present in the CellML API).

An up-to-date list of software supporting SED-ML is available from the Showcases on the SED-ML web page (<http://sed-ml.org>).

Sleep, Neural Population Models of

Andrew J. K. Phillips

Division of Sleep Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA

Definition

A neural population model of sleep is a mathematical model of neural populations that regulate the timing and expression of sleep/wake patterns. Specific circuits and nuclei have been identified in the mammalian brainstem and hypothalamus that play a key role in modulating the brain's overall arousal state with a circadian (daily) rhythm. These neural populations have been the focus of most sleep modeling.

Detailed Description

Sleep is an arousal state characterized by physical inactivity, reduced sensitivity to environmental stimuli, and a range of characteristic physiological changes, including changes to the EEG associated with rapid eye movement (REM) and non-REM (NREM) sleep in mammals. Sleep is regulated by a variety of physiological and biochemical processes (Krueger et al. 2008; Saper et al. 2010), including specific neural populations in the brainstem and hypothalamus. Various mathematical models have now been developed, providing a conduit between the underlying physiology and the sleep/wake dynamics observed at the behavioral level.

The Sleep/Wake Switch

The arousal states of sleep and wakefulness typically manifest as global patterns of brain activity; notable exceptions to this rule are unihemispheric

Sleep, Neural Population Models of, Fig. 1 The brain's overall arousal state is modulated by ascending projections to the cortex and thalamus from nuclei in the brainstem and hypothalamus. These include (i) wake-promoting nuclei that release monoaminergic neurotransmitters (blue), the tuberomammillary nucleus (TMN), the ventral tegmental area (VTA), the dorsal raphe (DR), and the locus coeruleus (LC); (ii) wake-promoting and REM sleep-promoting nuclei that release acetylcholine (green), the laterodorsal tegmentum (LDT) and the

pedunculopontine tegmentum (PPT); and (iii) wake-promoting neurons in the lateral hypothalamus (yellow) that release orexin (Orx). These nuclei are all GABAergic inhibited by sleep-promoting neurons (red) in the ventrolateral preoptic area (VLPO) and median preoptic area (MnPO). Excitatory (pointed arrows) and inhibitory (rounded arrows) interactions between nuclei are indicated. Mutual inhibition between sleep-promoting and wake-promoting nuclei forms the basis for the sleep/wake switch

sleep (sleeping with one brain hemisphere) and local sleep (emergence of sleep-like activity patterns in overworked neural assemblies while the rest of the brain is awake), which demonstrate that sleep can in principle be regulated on more local scales. Global synchronization of sleep and wake states across brain regions is achieved by control systems in the brainstem and hypothalamus. As shown in Fig. 1, a group of monoaminergic, cholinergic, and orexinergic neural populations projects diffusely to the cortex and thalamus. The coherent activation of these populations modulates corticothalamic activity, so as to promote and sustain wakefulness.

A population of sleep-promoting neurons in the ventrolateral preoptic area (VLPO) and median preoptic area (MnPO) of the hypothalamus GABAergicly inhibits the wake-promoting monoaminergic, cholinergic, and orexinergic neural populations. Interestingly, the wake-promoting monoaminergic populations in turn inhibit the sleep-promoting VLPO/MnPO populations. This

mutual inhibition between sleep-promoting and wake-promoting neural populations provides a basis for a switch-like system, with stable sleep and wake states, and relatively rapid transitions between states (Saper et al. 2010). This system is called the *sleep/wake switch*.

Sleep-Regulatory Processes

Prior to the recent detailed mapping of sleep-regulatory circuits in the brain, mathematical models of sleep were developed. In the absence of physiological data, these models were phenomenological rather than physiological. The most influential of these models was the two-process model of sleep (Daan et al. 1984), which provided the conceptual basis for most subsequent models of sleep and human performance (Van Dongen 2004). The two-process model assumes that sleep can be understood in terms of two key sleep-regulatory processes: the circadian process

and the sleep homeostatic process. The circadian process represents an approximately 24-h biological rhythm in sleepiness and alertness, typically described by a periodic function or nonlinear oscillator. The sleep homeostatic process represents the increasing need to sleep the longer one is awake and the dissipation of this need the longer one is asleep, typically described by exponentially saturating functions.

The physiological basis for the circadian process has now been well elucidated. Circadian rhythms are generated endogenously on a molecular level by virtually all mammalian cells. These cellular rhythms are synchronized by a master circadian clock that resides in the suprachiasmatic nucleus (SCN) of the hypothalamus. SCN neurons act as tightly coupled circadian pacemaker cells, sending a robust circadian signal to many other brain regions. The SCN receives direct input from the retina, allowing it to entrain to the daily light/dark cycle (Foster and Kreitzman 2005).

The physiological basis for the sleep homeostatic process is still not well understood, but evidence points towards the accumulation of certain sleep-promoting factors in the brain during wakefulness. These substances include adenosine, nitric oxide, TNF- α , Interleukin-1, and prostaglandin D2 (Krueger et al. 2008).

Both the circadian and sleep homeostatic processes have been found to act on the neural populations in the sleep/wake switch (Pace-Schott and Hobson 2002). The SCN has multiple relays to both the sleep-promoting and wake-promoting neural populations. The sleep-promoting factor adenosine has also been found to have effects on the VLPO. The sleep/wake switch therefore provides a neural basis for the integration of the circadian and sleep homeostatic processes.

Neural Population Models of Sleep

In order to test the theoretical value of the sleep/wake switch theory of sleep regulation, and to link the dynamics of underlying neural systems to behavioral manifestations, various mathematical models of the neural populations in the sleep/wake switch have recently been developed

(Tamakawa et al. 2006; Phillips and Robinson 2007; Behn et al. 2007; Behn and Booth 2010; Rempe et al. 2010; Kumar et al. 2012; Sedigh-Sarvestani et al. 2012). These models have included different levels of detail in terms of the neural populations included, as well as slightly different mathematical formalisms, including neural mass, single neuron, and neural mass/neurotransmitter concentration implementations. Central to all of these models is mutual inhibition between sleep-promoting and wake-promoting neural populations, i.e., the sleep/wake switch.

Here, we present a simplified mathematical description of the core dynamics of these neural population models of the sleep/wake switch. We base our equations on the Phillips–Robinson model, since it is the simplest and most widely used of the models (Robinson et al. 2011).

We model two neural populations: a wake-promoting population (subscript w) and a sleep-promoting population (subscript s). Each population has a mean firing rate, Q_j , and a mean cell body voltage relative to resting, V_j . We assume that the firing rate is a sigmoidal function of voltage, $Q_j = S(V_j)$. We also assume that the postsynaptic effects on voltage for each population are proportional to the presynaptic firing rates. The dynamics can then be represented by a pair of coupled first-order differential equations,

$$\begin{aligned}\tau_w dV_w/dt + V_w &= v_{ws}Q_s + A, \tau_s dV_s/dt + V_s \\ &= v_{sw}Q_w + D(t),\end{aligned}$$

where τ_j is a time constant for the saturation time constant; $v_{ws} < 0$ and $v_{sw} < 0$ represent the strengths of the inhibitory synaptic connections between the two populations; A represents any constant net input to the wake-promoting population; and $D(t)$ represents the net drive to the sleep-promoting population from circadian and sleep homeostatic processes. In general, the circadian and sleep homeostatic processes could also have a direct effect on the wake-promoting population. Here, we consider the most simple case for analysis.

The dynamics of the neural populations occur on a timescale of milliseconds to minutes (determined by the τ_j parameters), whereas $D(t)$

varies on a daily timescale by definition. A timescale separation can therefore be performed, treating D as approximately constant on timescales relevant to neural dynamics (Fulcher et al. 2008). The system dynamics can then be summarized by the reduced manifold of equilibrium values for various fixed values of D , as shown in Fig. 2.

For reasonable parameter values, the reduced system has two stable states, corresponding to sleep and wake. For a certain intermediate range of values for D , the system is bistable. As D oscillates with a period of ~ 24 h, the system is dragged back and forth across the bistable region, resulting in daily transitions between sleep and wake. The model exhibits hysteresis, because the thresholds for sleep-to-wake and wake-to-sleep transitions are different, as shown in Fig. 2.

This hysteresis behavior describes the most basic, reduced dynamics of most neural population

models of the sleep/wake switch. Interestingly, these physiologically based models recapitulate the basic assumptions of the phenomenological two-process model: two separate thresholds for sleep-to-wake and wake-to-sleep transitions (Phillips and Robinson 2008; Rempé et al. 2010). In other words, these models provide a physiological justification for the two-process model, as well as providing new insights by explicitly modeling the underlying physiological dynamics.

Neural population models of the sleep/wake switch have been highly successful in reproducing and predicting many aspects of human sleep and circadian rhythms (Robinson et al. 2011). In addition, mathematical models have been developed to describe how modulation of the corticothalamic system can give rise to the neural activity patterns associated with sleep and wakefulness, as well as transitions between arousal states (Robinson et al. 2002; Hill and Tononi 2005; Steyn-Ross et al. 2005; Deco et al. 2013). Linking corticothalamic and subcortical models poses a significant theoretical and numerical challenge due to their inherently different spatiotemporal scales, but such models are on the horizon (Robinson et al. 2010).

Sleep, Neural Population Models of, Fig. 2 If the sleep drive, D , is assumed to be slowly varying, the model dynamics can be visually summarized in terms of the equilibrium values for the wake-promoting population firing rate, Q_w , and the sleep-promoting population firing rate, Q_s . When the drive for sleep is low, the model has a stable wake state, with high Q_w and low Q_s . When the drive for sleep is high, the model has a stable sleep state with low Q_w and high Q_s . For an intermediate range of drive values, the model is bistable, with stable sleep and wake states. Saddle node bifurcations occur at critical thresholds (dotted lines). The stable wake and sleep branches are linked by an unstable equilibrium branch within the bistable zone. As D slowly oscillates on a daily timescale, the model therefore undergoes hysteresis as it is dragged across the thresholds where sleep and wake states become unstable

Recent Findings

Neural population models of the sleep/wake switch have been highly successful in reproducing and predicting many aspects of human sleep and circadian rhythms. Specifically, models of the sleep/wake switch have been used to understand the physiological mechanisms that underlie interindividual (Phillips et al. 2010a; Robinson et al. 2011) and interspecies (Phillips et al. 2010b, 2013) differences in sleep timing and duration. They have been used to reproduce normal human sleep (Phillips and Robinson 2007) and mouse sleep (Behn et al. 2007), as well as the effects of neurotransmitter microinjections (Behn and Booth 2010). They have also been applied to predicting human performance, including the effects of sleep deprivation (Fulcher et al. 2010) and caffeine on subjective fatigue (Puckeridge et al. 2010) and the effects of shiftwork on performance (Postnova et al. 2012).

Given the current uncertainty regarding the physiological mechanisms that underlie the REM/REM sleep cycle, neural population models have also been used to probe the possible dynamics of the system. This has led to concrete hypotheses regarding physiological mechanisms and circuits that could potentially generate the REM/NREM sleep cycle (Rempe et al. 2010; Behn and Booth 2012; Behn et al. 2013). Sleep/wake switch models have also recently been applied to reproducing the desynchronization of sleep/wake cycles from the circadian process that can occur when individuals are completely isolated from environmental time cues and are free to self-select their sleep/wake timings (Phillips et al. 2011; Gleit et al. 2013).

In addition, mathematical models have been developed to describe how modulation of the corticothalamic system can give rise to the neural activity patterns associated with sleep and wakefulness, as well as transitions between arousal states (Robinson et al. 2002; Hill and Tononi 2005; Steyn-Ross et al. 2005; Deco et al. 2013). Linking corticothalamic and subcortical models poses a significant theoretical and numerical challenge due to their inherently different spatiotemporal scales, but such models are on the horizon (Robinson et al. 2010).

Slow Feature Analysis

Laurenz Wiskott

Institut für Neuroinformatik, Ruhr-Universität Bochum, Bochum, Germany

Definition

Slow feature analysis (SFA) is an unsupervised learning algorithm for extracting slowly varying features from a multidimensional input signal in time. It is not based on low-pass filtering, i.e., temporal averaging, but combines input components of single time steps into temporally stable features. SFA can be used for nonlinear dimensionality reduction and learning of invariant representations. Algorithmically, it is closely related to principal component analysis (PCA).

Detailed Description

Slowness Principle

The slowness principle is based on the observation that different representations of a sensorial input vary on different time scales. For instance, a zebra grazing in the savanna is a scene that changes slowly. This scene is represented in the eyes of an observer in terms of activities of retinal receptors, which, due to the black-and-white stripes of the zebra, change quickly between high and low values whenever the zebra moves or the gaze of the observer changes. However, in higher brain areas of the observer, there is a high-level representation of the zebra grazing, which changes slowly again. This difference in time scales is true for most dynamic scenes. The slowness principle therefore states that high-level representations can be learned from the receptor

activities simply by extracting features that vary slowly over time (without using the trivial option of low-pass filtering).

The idea of the slowness principle has probably first been mentioned by Geoffrey Hinton in 1989; early algorithms were presented by Peter Földiák and by Graeme Mitchison, both in 1991; slow feature analysis (SFA) has first been introduced by Laurenz Wiskott in 1998; see (Wiskott et al. 2011) for references.

Slow Feature Analysis

Most learning algorithms based on the slowness principle are online learning rules, i.e., they improve the extracted features incrementally with each time step of the training data. Slow feature analysis (SFA) (Wiskott et al. 2011) in contrast is an algorithm that takes all training data into account at once.

SFA first uses PCA to normalize the input signal such that it has zero mean and unit variance in all directions, which is also known as whitening or sphering. It then calculates the time derivative (in the discrete case the difference between successive time points) of the whitened signal and uses PCA again to find the directions of smallest variance, which are the directions of slowest variation and correspond to the slow features to be extracted.

As SFA is based on PCA, it is basically a linear algorithm. However, one typically applies a pre-defined set of nonlinear functions to the input signal first, which is known as nonlinear expansion, and then applies SFA to this expanded input signal. Thus, SFA learns linear combinations of fixed nonlinear functions, which results in nonlinear functions to extract features from the input.

It has been shown analytically that SFA is closely related to spike-timing-dependent plasticity (STDP) (Sprekeler et al. 2007).

Applications in Computational Neuroscience

SFA has been developed for learning invariant representations of moving objects in a feedforward model of the visual system. It has been shown that a hierarchical network of SFA nodes extracts features from a video signal of moving objects that permit invariant object

recognition with a simple classifier and also extraction of positional and pose information with linear regression (Wiskott et al. 2011). Interestingly, on the first SFA layer units share many properties with complex cells in the primary visual cortex, such as phase invariance, orientation selectivity, and frequency tuning. One also finds end- and side-inhibited units there. Complex cell-like units emerge also if learning is based on simulated retinal waves rather than moving objects (Dähne et al. 2014).

If combined with independent component analysis, an SFA network trained with input from a simulated rat running around in a static environment develops units that behave like place cells and others that behave like head-direction cells in the hippocampal formation of rats (Wiskott et al. 2011). Place cells fire if a rat is at a particular location independently of its head direction; head-direction cells fire if a rat is oriented in a particular direction independently of its location. SFA can extract location and head direction because these variables vary slowly compared to individual pixel values of the visual input sequence as the rat runs through the environment.

SFA has also been used for technical applications (Escalante-B and Wiskott 2012).

Slow Oscillations and Epilepsy: Network Models

Alain Destexhe

Unit of Neuroscience Information and Complexity (UNIC), Paris-Saclay University, Institute of Neuroscience (NeuroPSI), Centre National de la Recherche Scientifique (CNRS), Gif-sur-Yvette, France

Definition

Network models are very useful tools to investigate the genesis of oscillatory behavior such as epileptic seizures. During many types of seizures, the brain produces oscillatory spike-and-wave discharges, which are particularly prominent for absence seizures. It was found that the thalamocortical mechanisms leading to spindle oscillations and their large-scale synchrony can explain spike-and-wave oscillations, if the excitability of the cerebral cortex is augmented. These pathological oscillations can be reproduced by network models involving the reciprocal interaction between thalamus and cortex.

Detailed Description

Introduction

Many types of epileptic seizures display very synchronized oscillations producing a typical electroencephalogram (EEG) pattern consisting of one or several sharp deflections (“spikes”) followed by a surface-positive “wave.” Spike-and-wave patterns of similar characteristics are also seen in a number of experimental models in cats, rats, mice, and monkeys, as well as in many other types of epilepsies. In some of these experimental models, it was shown that the critical regions involved are the thalamus and neocortex and that the genesis of spike-and-wave activity shares common mechanisms with sleep spindle oscillations, which are generated in the thalamus. Computational models have explored mechanisms for such spike-and-wave activity, as reviewed here.

The Cellular Bases of Spike-and-Wave Discharges in Cortex

Computational models have first explored the cellular pattern needed to generate spike-and-wave EEG or local-field potentials. Using a simple biophysical model of cortical network with excitatory and inhibitory neurons (Destexhe 1998), it was found that spike-and-wave LFP patterns can be generated if all cells fire in synchrony (“spike” component), followed by a hyperpolarization mediated by K^+ conductances (“wave” component). The synchronized discharge during the “spike” was indeed found in many different experimental models of seizures (reviewed in Destexhe 2013), while the hyperpolarization during the “wave” remains poorly studied. Intracellular recordings during spike-and-wave seizures showed that the “wave” is correlated by hyperpolarization, which was interpreted as due to a mixture of disfacilitation and K^+ currents (Neckelmann et al. 2000). The model suggests that this slow K^+ conductance can be due to two different mechanisms: either it can be generated by the slow voltage-dependent K^+ conductances responsible for spike-frequency adaptation in pyramidal neurons. In this case, the strong firing during the “spike” maximally activates these adapting currents, which then produce the slow hyperpolarization. Another possible origin is synaptic; the strong firing may massively activate the slow type of GABAergic inhibition, acting on $GABA_B$ receptors, which also cause a slow activation of K^+ channels.

Hypersynchronized Slow Oscillations in the Thalamus

Many experimental evidences show that thalamic circuits are implicated in seizure generation (reviewed in Gloor and Fariello 1988; Crunelli and Leresche 2002). It was found that if convulsants are applied to the thalamus *in vitro*, blocking $GABA_A$ receptors, they induce the production of a slow and synchronized oscillation at around 3 Hz and are dependent on $GABA_B$ receptors (von Krosigk et al. 1993). Although it is tempting to associate the origin of the seizure and the spike-and-wave oscillation to the thalamus, it is not the case, because this slow oscillation was shown to

be different from spike-and-wave oscillations *in vivo* (Steriade and Contreras 1998). This slow oscillation was simulated by network models of thalamic circuits (Destexhe et al. 1993, 1996; Golomb et al. 1996) and was due to the mutual interaction between thalamic relay and reticular neurons, involving GABA_B receptors.

Model of Spike-and-Wave Discharges in the Thalamocortical System

Experimentally, it was shown that the cerebral cortex is the key to the induction of seizures. In cats, different experimental manipulations of cortical excitability lead to spike-and-wave seizures, but the *physiologically intact* thalamus is necessary (Gloor and Fariello 1988). In rat models of absence seizures, a focus of increased excitability was found in cortex (Meeren et al. 2002; Polack et al. 2007), but the thalamus was also necessary for seizure generation (Vergnes and Marescaux 1992). These results were replicated by computational models of thalamic and cortical networks, endowed with the different receptor type present as well as the intrinsic cellular properties of thalamic and cortical cells (Destexhe 1998, 1999). This model is explained below.

The main hypothesis explored by this model was that seizure generation uses the oscillatory-generating mechanisms present in the thalamus but with an over-excitable cortex. In “control” conditions, the network model generates spindle oscillations. As shown in detail in another entry (► “Spindle Oscillations: Models”), spindle oscillations are generated by thalamic circuits and can be modeled by thalamic networks. In the thalamocortical system, the cortex plays an essential role in synchronizing the thalamic-generated oscillations, as also described in detail in another entry (► “Corticothalamic Feedback: Large-Scale Synchrony”). In this case, the models established that the most efficient way for the cortex to control the thalamic oscillation and organize its large-scale synchrony is to evoke strong inhibition in the thalamus (Destexhe et al. 1998).

This “inhibitory dominant” character of the corticothalamic interaction is fundamental to explain seizures. While this cortically evoked thalamic inhibition is mostly mediated by GABA_A

receptors in normal conditions, it may be different in pathological conditions. If the cortex is hyper-excitable, the exaggerated corticothalamic feedback will be strong enough to activate GABA_B receptors (due to their nonlinear activation properties – see Destexhe and Sejnowski 1995). This activation of slow GABA_B inhibition will “force” the thalamus, although physiologically intact, to oscillate at a slower and more synchronized frequency around 3 Hz (Destexhe 1998).

This mechanism was tested by simulating networks of thalamic and cortical cells, with the different receptor types present, and the system was able to generate hypersynchronized oscillations at 3 Hz when solely the cortex was affected (its excitability was augmented by diminishing intracortical inhibition). Remarkably, this model generated 2–3 Hz oscillations with spike-and-wave patterns in the calculated LFPs (Destexhe 1998).

A very similar mechanism was found for faster oscillation frequencies typically observed in rodents (Destexhe 1999). In this case, the total conductance of GABA_B inhibition in the thalamus had to be weaker, preventing the thalamus to oscillate at 3 Hz. Thus, this model predicts that the ~3 Hz spike-and-wave of cats, monkey, and man and the ~8 Hz spike-and-wave seizures of rats and mice have a common cellular mechanism but different respective conductances of GABA_A and GABA_B receptor-mediated inhibition in the thalamus. This prediction still awaits to be tested.

Testing the Mechanism in Thalamic Slices

The main prediction of this thalamocortical model of seizures is that a too-strong corticothalamic feedback should be able to switch the *intact* thalamus to oscillate at 3 Hz (Destexhe 1998), a frequency which is not normally seen in the physiologically intact thalamus. This prediction was tested in thalamic slices, where the corticothalamic fibers can be stimulated electrically. It was found by two independent studies (Bal et al. 2000; Blumenfeld and McCormick 2000) that, indeed, strong stimulation of corticothalamic fibers can “force” the thalamus to oscillate at 3 Hz and that this forcing is dependent on GABA_B receptors. It was also shown that

the “forced” 3 Hz oscillations are more synchronized than the natural 10 Hz spindle rhythm produced by the same thalamic circuits. These findings are all in agreement with the predictions of the model and therefore support the view that 3 Hz hypersynchronized oscillations can be generated by the thalamus subject to a hyperexcitable cortex.

Discussion

In conclusion, computational models have provided a plausible explanation for a number of contrasting experimental results. First, the thalamus can produce a slow oscillation around 3 Hz, where GABA_B receptors are important, but this oscillation is not the primary cause for ~3 Hz spike-and-wave discharges seen in epileptic seizures. The model can reproduce the experiments showing that the disinhibited thalamus does not produce spike-and-wave in cortex.

Second, seizures can be generated by a hyperexcitable cortex, but the intact thalamus is necessary. The generation of seizures depends on an interaction between cortex and thalamus. An essential ingredient in this interaction is that the corticothalamic feedback must be very efficient in evoking inhibition in the thalamus. If this is the case, the models show that a hyperexcitable cortex will generate a feedback strong enough to recruit GABA_B receptors in the thalamus and “force” the slow oscillatory mode (although the thalamus is physiologically intact).

If these ingredients are assembled in a thalamocortical model, ~3 Hz spike-and-wave oscillations can be generated if the cortex alone is made hyperexcitable, but the thalamus is kept physiologically intact (Destexhe 1998). This thalamocortical mechanism is dependent on the presence of GABA_B receptors in the thalamus, which are responsible for the ~3 Hz oscillation of the entire system. If the thalamus has weak GABA_B-mediated inhibition, then the hyperexcitable system oscillates at a faster frequency, around 8 Hz, as found in rodents. Thus, the models predict that a common mechanism underlies absence seizures in all mammals but that the

exact oscillation frequency will be dependent on the balance between GABA_A and GABA_B receptors in the thalamus (Destexhe 1999).

Finally, this model is compatible with the finding that a focus in cerebral cortex is associated to absence seizures in rats (Meeren et al. 2002). It was found that deep (layers 5–6) cortical neurons are hyperexcitable and seem to lead the discharges during ictal activity (Polack et al. 2007). As layer 6 neurons project to thalamus, this finding is consistent with the idea that an excessive corticothalamic feedback may be a primary cause for absence seizures.

[Up and down state models](#)

Definition

Several computational models have been proposed to describe the generation of spontaneous slow oscillations, or up and down state dynamics, in neuronal circuits of the cerebral cortex. Most models rely on strong excitatory feedback to generate reverberatory dynamics in the up state, which are then quenched by some negative feedback mechanism to form down states. The specific mechanisms responsible for triggering the transitions between up and down states distinguish these models. In addition, some models have been proposed that emphasize the role of thalamocortical loops in generating this spontaneous activity.

Detailed Description

During non-REM sleep and under most anesthetics, cortical network dynamics exhibit slow oscillations or up and down state switching (see ► [“Slow Oscillations: Physiology”](#)). This pattern of activity has been the subject of numerous computational models, which have formulated quantitative accounts of the possible mechanisms that participate in their generation.

The models contemplate two main mechanisms to ignite up states. One set of models proposes that down states end as a result of the recovery of a fatigue mechanism accumulated during up states, such as some activity-dependent potassium current (Compte et al. 2003; Destexhe 2009), or short-term synaptic depression (Mejias et al. 2010). Spontaneously active excitatory neurons, possibly in specific layers (Destexhe 2009), are then responsible for starting a new up state. This links down state duration to the time constant of recovery of such fatigue mechanism. On the other hand, up states could be started by input fluctuations that impose a transition from a stable down state to the up state. Mechanistically, these fluctuations could be due to spontaneous synaptic release (Timofeev et al. 2000; Holcman and Tsodyks 2006; Mejias et al. 2010) or to external fluctuating inputs (Kepecs and Raghavachari 2007; Hughes et al. 2002; Mattia and Sanchez-

Vives 2012). Down state duration in these scenarios is highly variable.

Similarly, the extinction of up states has also been modeled through either deterministic or stochastic processes. Mechanisms relying on activity-dependent negative feedback bring the up state deterministically to the point of sudden transition to the down state (Fig. 1b, d). Such negative feedback can be due to activity-dependent potassium currents (Compte et al. 2003; Hill and Tononi 2005), short-term synaptic depression (Holcman and Tsodyks 2006), short-term synaptic facilitation to interneurons (Melamed et al. 2008), or slow

GABA_B feedback inhibition (Parga and Abbott 2007). On the other hand, endogenous fluctuations can also induce transitions from the up to the down state (Fig. 1a, c), in the form of stochastic inputs nonlinearly gated by NMDA receptors (Kepecs and Raghavachari 2007) or as a result of the stochastic dynamics of the firing rate in small populations (Mattia and Sanchez-Vives 2012). Note, however, that these recurrent networks impose complex interdependencies between all these mechanisms: as an example, short-term depression promotes up-to-down transitions on its own (Holcman and Tsodyks 2006), but prevents them when

Slow Oscillations: Models, Fig. 1 Mechanistic scenarios for up and down state switching in a bistable recurrent network with adaptation currents. (a) For fixed values of the adaptation current, the recurrent network stabilizes at firing rates that trace a cubic nullcline with a stable upper branch (up states) and a stable lower branch (down states). Unstable solutions are marked with a *dashed line*. In a range of values of adaptation (bistable range), the system features bistability between the two states. For very weak or absent adaptation dynamics, the systems sit at a fixed value of adaptation current (*gray line*) giving rise to two stable states. In this scenario, transitions between states can only occur if external fluctuations arrive that impose a

change of state (*wiggled arrows*). (b) For strong adaptation, the nullcline defining the values of adaptation current that are steadily maintained at a given neuronal firing rate (*gray line*) does not intersect the network stability nullcline (*black cubic line*), and the system cycles periodically between up and down states. (c) Weaker adaptation makes the adaptation nullcline intersect the network nullcline in the upper branch and up states become stable. Only strong fluctuations will induce an up-to-down transition. (d) Starting from the condition in b, a slight hyperpolarization to all neurons in the network makes the down state stable, and down-to-up transitions now depend on strong episodic fluctuations

combined with adaptation currents (Benita et al. 2012).

All the models proposed share a common mechanistic substrate: up and down dynamics emerge from an underlying bistability between these states that gets perturbed by additional slow or episodic mechanisms. This general dynamic picture can be illustrated graphically for a network with recurrent excitation and slow rate adaptation mechanisms (Fig. 1; Latham et al. 2000), from which it can be generalized to other mechanisms. The bistability condition implies that two stable states are accessible for a range of values for the adaptation current (bistable range, Fig. 1a). Thus, for a fixed level of adaptation (gray line in Fig. 1a), only random occasional fluctuations in excitability can impose a transition between the stable states (Fig. 1a). Adaptation mechanisms, however, can modify the system so that it no longer has stable fixed points but exhibits an oscillatory behavior. During this oscillation the network shows slow drifts along the up and down branches as adaptation builds up and decays, respectively (Fig. 1b). Depending on the magnitude of adaptation and the level of external drive to the network, transitions may occur deterministically due to the slow dynamics of adaptation (Fig. 1b, down-to-up in Fig. 1c and up-to-down in Fig. 1d), or they may be induced by episodic fluctuations that trigger transitions to escape from a stable state (Fig. 1a, up-to-down in Fig. 1c and down-to-up in Fig. 1d).

The mechanism by which bistability is achieved in the cortical network is generally assumed to be excitatory synaptic reverberation within the local circuit (Timofeev et al. 2000; Compte et al. 2003; Bazhenov et al. 2002; Hill and Tononi 2005; Holcman and Tsodyks 2006; Melamed et al. 2008; Mejias et al. 2010; Mattia and Sanchez-Vives 2012). Indeed, the bistable range of the cubic nullcline in Fig. 1 grows larger with stronger recurrent connections. This is consistent with the strong and dense connectivity in cortical circuits and explains parsimoniously the sensitivity of up states to excitatory synaptic blockers and the resilience of up-and-down membrane voltage dynamics to the hyperpolarization of individual neurons. Alternative mechanisms

for such bistability are nonlinearities in NMDA receptors (Kepecs and Raghavachari 2007) or interactions between intrinsic ionic channels in individual neurons (Hughes et al. 2002; Parga and Abbott 2007). Also, intrinsic mechanisms such as persistent sodium currents have been invoked to achieve and maintain reverberatory activity in the up state (Timofeev et al. 2000; Bazhenov et al. 2002; Hill and Tononi 2005).

Several mechanisms have been proposed to explain that firing rates during up states remain low despite strong excitatory feedback in the network. Here, the most common mechanism invoked is inhibitory feedback from the local microcircuitry. A strong coupling with a local inhibitory population can control firing rates while recurrent excitation maintains up states. Consistent with this, blockers of inhibitory synaptic transmission increase the firing rates in up states (Sanchez-Vives et al. 2010). It has been argued that short-term synaptic depression can also counteract strong excitation and maintain low firing rates in up states (Holcman and Tsodyks 2006).

Finally, computational models have also addressed the role of the thalamocortical loop in slow oscillations. While thalamocortical neurons can modulate cortically generated slow oscillations (Bazhenov et al. 2002; Hill and Tononi 2005), some computational studies attribute an active role of thalamocortical neurons in maintaining these dynamics. In particular, intrinsic oscillatory mechanisms in thalamocortical neurons may take part in up state initiation in cortical networks (Hughes et al. 2002).

Synonyms

Slow waves; Up and down states

Definition

Slow oscillations are the coordinated activity of large populations of neurons consisting of an alternation of active periods (Up states) and silent periods (Down states). These oscillations occur with a slow frequency (≤ 1 Hz) in the corticothalamocortical network during slow-wave sleep and deep anesthesia, and they spontaneously occur also in cortical slices. This rhythmic activity emerges in the cortical network when there are no other driving inputs, and it can be considered its default activity. During the active periods, or Up states, neocortical neurons (both excitatory and inhibitory) are depolarized, receive barrages of synaptic inputs, and fire action potentials. During Down states neurons remain hyperpolarized and the synaptic activity is almost nonexistent. This “on-and-off” synaptic activity results in a bimodal distribution of the membrane potential values, an intracellular signature of slow oscillations. During the active or Up states, the activity expresses coherent oscillations at high frequencies in the beta (15–30 Hz) and gamma (30–90 Hz) range.

Detailed Description

Background

Slow waves during quiescent sleep have been recorded since the early days of electroencephalogram (EEG) in the 1930s. However, the first detailed characterization of the cortical slow oscillation was published by Steriade and collaborators in 1993 (Steriade et al. 1993a, b, c). In these studies, the frequency of the slow oscillation was described to be between 0.2 and 0.5 Hz, and generally below 1 Hz in the cat.

Origin

Slow oscillations are prominent in the corticothalamocortical loop, and they originate in the cortical recurrent connectivity. The initial observation that slow oscillations persisted in the cortex after destruction of the connected thalamus (Steriade et al. 1993c) while the opposite was not true (Timofeev and Steriade 1996)

was strongly suggestive of their cortical origin. The fact that cortical slices *in vitro* spontaneously generate slow oscillations highly similar to the ones in the whole brain is also a strong evidence in favor of their cortical origin (Sanchez-Vives and McCormick 2000; McCormick et al. 2003). *In vivo* cortical slabs (Timofeev et al. 2000), disconnected from the surrounding tissue, can as well generate slow oscillations. However, the cortex is reciprocally connected to subcortical structures, and the emergent pattern recorded *in vivo* is shaped as a result of this interaction. The interaction with the thalamus is especially relevant, since it also displays slow oscillations coordinated with the cortical ones (Steriade et al. 1993b; Crunelli and Hughes 2010). Detailed analysis has revealed that the inactivation of the thalamus results in a decreased frequency of the cortical slow oscillations (David et al. 2013).

Mechanisms of Initiation of the Up States

Simultaneous recordings from different cortical layers provide a layer profile of activation during Up states. Cortical recordings from different species (cats, ferrets, rodents) both *in vivo* and *in vitro* agree on the leading role of infragranular layers – in particular layer 5 – in the initiation of Up states (Sanchez-Vives and McCormick 2000; Sakata and Harris 2009; Chauvette et al. 2010). Layer 5 neurons not only lead Up states, but also have a more intense and longer discharge during each Up state, while layer 2/3 neurons display a weaker and shorter firing (Sanchez-Vives and McCormick 2000; Sakata and Harris 2009). Furthermore, optogenetic activation of layer 5 – but not of layer 2/3 neurons – is enough to initiate Up states and entrain slow oscillations (Beltramini et al. 2012; Stroh et al. 2013).

Different mechanisms have been proposed for layer 5 neurons to initiate the firing that by reverberation in close loops results in the initiation of new waves. A larger intrinsic excitability of layer 5 neurons drives them to start firing during Down states (Sanchez-Vives and McCormick 2000; Compte et al. 2003; Sakata and Harris 2009), stochastic release of synaptic vesicles (Timofeev

et al. 2000) and specific pacemaker cells (Le Bon-Jego and Yuste 2007).

Only in human cortex Up states are reported to start in supragranular layers (Cserscsa et al. 2010), a critical difference in cortical function that requires further study.

Excitatory/Inhibitory Balance During Up States

A key element in the balance and control of either spontaneous emergent or evoked cortical activity is the relation between excitation and inhibition. Both excitatory and inhibitory neurons fire during Up states (Steriade et al. 1993c). Conductance measurements during Up states reveal that the weights of excitation and inhibition are well balanced *in vivo* (Haider et al. 2006) and similarly *in vitro* (Shu et al. 2003) as argued theoretically (Compte et al. 2003). Changes in excitatory and inhibitory conductance *in vitro* reveal that both increase and decrease at the beginning/end of Up states occur in close association with each other (Shu et al. 2003). The timing of individual excitatory and inhibitory synaptic events also reveals a remarkable coincidence in the accumulation of both excitatory and inhibitory synaptic events during the rise of an Up state both *in vitro* and *in vivo*, although it is 1.4 times faster *in vivo* (Compte et al. 2009). A similar coincidence also occurs at the termination of the Up state. Such interlocking in time of excitation and inhibition is also found in simultaneous recordings of nearby pairs of cortical neurons (Okun and Lampl 2008).

Both the excitatory and the inhibitory synaptic conductances are high at the beginning of the Up state, and they tend to progressively decrease, but their ratio remains constant and close to 1 in anesthetized and *in vitro* preparations (Shu et al. 2003; Haider et al. 2006). Other studies report that the inhibitory conductance is much larger than the excitatory conductance during Up states in natural sleep (Rudolph et al. 2007).

Mechanisms of Termination of the Up States

Several mechanisms have been proposed that could account for the termination of Up states.

They include arrival of excitation (Shu et al. 2003; Haider et al. 2006), synaptic depression (Bazhenov et al. 2002), thalamic disfacilitation (Contreras et al. 1996), activation of K^+ currents (Sanchez-Vives and McCormick 2000; Compte et al. 2003), or extracellular K^+ dynamics (Frohlich et al. 2006). The time course of the slow afterhyperpolarization observed in intracellular recordings during Down states (e.g., Fig. 7c in Sanchez-Vives and McCormick 2000; Contreras et al. 1996) suggests that slow K^+ currents can be contributing to the termination of Up states and maintenance of Down states. Different mechanisms involving K^+ currents have been proposed, including ATP-dependent K^+ current (Cunningham et al. 2006), GABA_B receptor-mediated responses (Mann et al. 2009), and Ca^{2+} - and Na^+ -dependent K^+ currents (Sanchez-Vives and McCormick 2000). Slow K^+ -mediated afterhyperpolarizations are blocked by neurotransmitters (acetylcholine, noradrenaline) that control the transition from sleep to awake (Schwindt et al. 1988; Brumberg et al. 2000), providing a mechanism for stopping the bistability when entering the awake state.

Propagation

Slow waves propagate along the cortical network. Propagation occurs both in vivo during slow-wave sleep or anesthesia and also in the cortex in vitro. During wave propagation, infragranular layers lead the front of the wave, although columnar interactions between supragranular and infragranular layers are required for maintaining correct propagation speed (Wester and Contreras 2012). The propagation is continuous, and locally generated Up states can be recorded along the propagation in all cortical layers. The reported values of the propagation speed vary across species and conditions: 1.2–7 m/s in humans during slow-wave sleep (Massimini et al. 2004), 100 mm/s in the anesthetized cat (Steriade et al. 1993c), around 30 mm/s in the anesthetized mouse (Ruiz-Mejias et al. 2011; Stroh et al. 2013), and 10 mm/s in the neocortical slices in vitro (Sanchez-Vives and

McCormick 2000). In paleocortex in vitro, such as the olfactory cortex, propagation is an order of magnitude faster (114 mm/s) (Sanchez-Vives et al. 2008). Cortical inhibition slows down propagation (Trevelyan et al. 2007), and the gradual blockade of GABA_A-mediated inhibition progressively increases the propagation speed (Sanchez-Vives et al. 2011). Once the wave is transformed into an epileptiform discharge due to inhibition removal, propagation speed increases by one order of magnitude (Sanchez-Vives et al. 2011).

Fast Rhythms During Up States

During Up states the in vivo network activity is temporally structured in fast oscillations in the beta (15–30 Hz) and gamma (30–90 Hz) range (Steriade et al. 1996; Hasenstaub et al. 2005; Ruiz-Mejias et al. 2011). Inhibitory synaptic potentials carry the great majority of power in this high-frequency range, often synchronously inhibiting nearby pyramidal cells (Hasenstaub et al. 2005).

The emergent activity of the cortical network in vitro can also be synchronized in these high frequencies as a result of pharmacological activation, typically with cholinergic or metabotropic agonists, kainate, or electrical tetanic stimulation of the tissue (Buhl et al. 1998; Cunningham et al. 2003; Hasenstaub et al. 2005; Traub et al. 2005). Although these neuromodulators potently modulate high frequencies, robust beta/gamma oscillations emerge already during physiological network function in vitro in the absence of externally applied neuromodulatory agents and without any particular stimulation pattern (Compte et al. 2008). The systematic comparison across different cortical areas of beta and gamma power in the mouse in vivo reveals that prefrontal cortex Up-state activity presents significantly stronger fluctuations than in motor, somatosensory, and visual cortex, in particular in the gamma range (one order of magnitude larger power) (Ruiz-Mejias et al. 2011; Fig. 1).

Sodium Channels

Dominique Engel

GIGA-Neurosciences, University of Liège, Liège, Belgium

Synonyms

[Na⁺ channels](#); [Voltage-gated Na⁺ channels](#)

Definition

Sodium channels are proteins enched in the cell membrane of both excitable and nonexcitable cells. They are in general composed of two different types of proteins, termed subunits, an alpha (α) and two beta (β) subunits. The arrangement of the α subunit across the cell's membrane enables the formation of an aqueous tunnel termed channel linking the cells interior and the extracellular space. Changes in the transmembrane voltage govern channel gating. When the channel is open, almost exclusively sodium (Na⁺) ions flow through the channel (Fig. 1a). The Na⁺ ion flow through the channel can be blocked by tetrodotoxin (TTX), a specific and widely used puffer fish toxin.

Sodium Channels, Fig. 1 Structure and function of sodium channels. (a) Schematic representation of a sodium channel enmeshed in the plasmic membrane of a cell. When the membrane potential is close to rest, Na⁺ ions are flowing inside the cell due to the driving force of Na⁺ ($V_m - E_{Na}$). (b) Conductance model for sodium channels. E_{Na} is the equilibrium potential for Na⁺ represented by the

battery and g_{Na} is the variable conductance of Na⁺ channels which depends on time and potential represented by the arrow. C_m is the capacitance of the membrane. (c) Transmembrane organization of the α and β subunits of the sodium channel. (Modified from Catterall (2001) with permission)

Functional properties of sodium channels can be translated into an electrical conductance model consisting of a battery in series with a resistor and an arrow indicating a time- and voltage-dependent conductance (Johnston and Wu 1995; Hille 2001; Fig. 1b).

Detailed Description

Structure and Function of Sodium Channels

Sodium channels are proteins enmeshed in the cell membrane of different excitable cell types including neurons of the central and peripheral nervous system and muscle cells including skeletal, smooth, and cardiac muscle cells but also in various nonexcitable cells (Black and Waxman 2013). They are composed of a principal alpha subunit responsible for the formation of the pore and beta auxiliary subunits implicated in the

regulation of channel function (Johnston and Wu 1995; Hammond 2001; Catterall 2012; Fig. 1c). The alpha subunit exists in distinct isoforms (Table 1) and consists of a long chain of about 2000 amino acids arranged in four repetitions of a specific sequence of amino acids termed homologous domain (I, II, III, and IV). Within each domain, the sequence forms six transmembrane segments (S1–S6). The four homologous domains are presumably arranged across the membrane to form a central pore bordered by S6 segments. S4 segments are important for the gating as they are composed by positively charged amino acids and thereby are believed to represent the voltage sensor of the channel (Johnston and Wu 1995; Hammond 2001; Hille 2001; Catterall 2012). In neurons, sodium channels are present generally in each subcellular compartment (soma, axon, and dendrites). But a nonhomogeneous distribution of the channels may exist in the different neuronal

Sodium Channels, Table 1 Mammalian sodium channel properties

CNS central nervous system, PNS peripheral nervous system, TTX tetrodotoxin (specific blocker of sodium channels). A more detailed description of the diversity of Na⁺ channels is reviewed in (Goldin 2002). A detailed analysis of the localization of Na⁺ channels is reviewed in (Vacher et al. 2008)

compartments (Magee 2008; Vacher et al. 2008). The function of Na⁺ channels in excitable cells is to permit an entry of positive charges into the cell in order to depolarize the membrane and to generate action potentials (APs). Na⁺ channel permeability is essential for the initiation and the propagation of APs in excitable cells, and their open probability increases largely during the upstroke of APs. Na⁺ channels mentioned above and in the two following paragraphs have fast activation and inactivation and are therefore termed transient Na⁺ channels. Two additional Na⁺ currents may be expressed by excitable cells, termed “resurgent” and “persistent,” passing current during membrane potential repolarization after brief depolarizations (Cruz et al. 2011) and passing noninactivating current, respectively (Kiss 2008). Dysfunctions of sodium channels (sodium “channelopathies”) cause a variety of diseases among which are epileptic syndromes and muscle diseases (Waxman 2001; Savio-Galimberti et al. 2012).

Patch-Clamp Recordings of Single-Channel and Macroscopic Sodium Currents

The development of the patch-clamp technique gave the opportunity to measure directly the unitary Na⁺ current flowing through a single

sodium channel (Sakmann and Neher 1995). Unitary Na⁺ currents have a typical rectangular time course representing transitions between open and closed states of the channel. Unitary currents are therefore all-or-none events, and their peak amplitude is voltage-dependent according to Ohm’s law:

$$i_{Na} = \gamma_{Na}(V_m - E_{Na})$$

where i_{Na} is the unitary Na⁺ current, γ_{Na} is the single-channel conductance, V_m is the membrane potential, and E_{Na} is the reversal potential of Na⁺ ions.

The summation of a large number of unitary Na⁺ currents results in a macroscopic Na⁺ current which corresponds nearly to the “whole-cell” current recorded in a cell. Unitary and macroscopic Na⁺ currents are proportional and related by the following equation:

$$I_{Na} = N \ p_{(t)} i_{Na}$$

where I_{Na} is the macroscopic current, N is the number of Na⁺ channels, and $p_{(t)}$ is the open probability at a time t . Mechanistically, the behavior of Na⁺ channels is characterized by transitions between three distinct states, an open state (O), a

Sodium Channels, Fig. 2 Conformational states in the Hodgkin Huxley formalism. Sequence of transitions of sodium channels through C, O and I states illustrated with the movement of the gating particles (*m* and *h*)

closed state (C), and an inactivated state (I). Transitions are illustrated by the scheme in Fig. 2.

Typically, the sodium channel switches from C to O on depolarization and rapidly back from O to C with repolarization when the depolarization time is very short. On sustained depolarization, the sodium channel closes more slowly and switches from O to I. The latter transition is termed inactivation and corresponds to a refractory state of the channel characterized by a non-passing ion state (Ulbricht 2005; Catterall et al. 2012). The probability of the Na⁺ channels being open increases with depolarization and the duration of the open state varies around a mean value termed mean open time. To be able to reopen after inactivation, sodium channels need to transit through the C state for a certain period of time, and this is achieved with membrane hyperpolarization (Hammond 2001). With fundamental work published in 1952, Hodgkin and Huxley interpreted the transitions between the conformational states of sodium channels with the movement of activation (*m*) and inactivation (*h*) gates regulating the permeability of the channel (Fig. 2; Johnston and Wu 1995; Koch 1999). In the Hodgkin–Huxley (HH) formalism, permeability

changes are described by ionic conductance which is voltage- and time-dependent:

$$g_{\text{Na}} = \bar{g}_{\text{Na}} m^3 h$$

from which the right side of the equation can be implemented in the equation describing the macroscopic Na⁺ current:

$$I_{\text{Na}} = \bar{g}_{\text{Na}} m^3 h (V_m - E_{\text{Na}})$$

where $\bar{g}_{\text{Na}}$ (g_{Na} “bar”) is the maximal value of the conductance and *m*, *h* represent the fraction of two distinct type of gating particles in the inside of the membrane.

Modeling Sodium Channel Conductance to Estimate Membrane Potential Changes

A detailed functional analysis of sodium channel properties is fundamental to understand the generation of APs in excitable cells. With their pioneer study, Hodgkin and Huxley proposed a quantitative model describing the permeability of sodium channels in terms of ionic conductance changes using experimental data. With this model, they could also predict the time course of APs. Without any knowledge about the structure of an ion channel, they predicted that sodium channels are gated by gating variables which are dependent on time and voltage and postulated that the transitions between open and closed states obey first-order kinetics (Johnston and Wu 1995; Destexhe and Huguenard 2001; Hille 2001; Koch 1999). While the HH formalism has still a large influence to describe channel functional properties and to predict AP time course, it is a macroscopic approximation (Catterall et al. 2012) and may have some limitations. For instance, the HH formalism is unable to describe the abrupt onset of APs of cortical neurons (Naundorf et al. 2006).

Alternatively, the gating of sodium channels in stochastic Markov models is described by transitions through a series of distinct conformational states. These models assume that the transitions between conformational states are memoryless and depend only on the current state (Destexhe and Huguenard 2001; Kispersky and White

2008). Markov models are thereby more precise to describe conformational changes of single channels (Destexhe and Huguenard 2001).

Software for Neuroimaging Data Analysis

Jean Baptiste Poline¹ and David Kennedy²

¹Henry H. Wheeler, Jr. Brain Imaging Center, Helen Wills Neuroscience Institute, University of California, Berkeley, CA, USA

²Department of Psychiatry, Division of Neuroinformatics, University of Massachusetts Medical Center, Worcester, MA, USA

Definition

Software is defined by as “a plan specification composed of a series of instructions that can be interpreted by or directly executed by a processing unit.” We define Software for Neuroimaging Data Analysis as software whose primary goal is to support the extraction of information, and ultimately knowledge, from data acquired by an imaging device used on the brain (of human or animal subjects).

Detailed Description

Introduction

Tell us what you think about neuroimaging software, and we will tell you who you are. To some,

using software to analyze data is little more than a technical step that stands between data acquisition and publishing. Doctoral students, postdocs, or technical assistants only need to operate the appropriate software, i.e., the script to run or the right sequence of buttons to press. To others, choosing, adapting, running, or developing the right software code is critical and requires investing significant time and resources.

Data analysis is one of the most time-consuming parts of neuroimaging research. While it can take, in general, months to acquire a small to medium dataset, it often takes years before the data are fully analyzed. It is not rare that specific software or methods have to be developed for a specific question or dataset. Data are typically reanalyzed several times in different ways, using different inputs or software options, influencing the interpretation or the type I error rate (Simmons et al. 2011). With the perspective of efficiency, if most of the time is spent on data analysis, sharpening these tools should be a priority. In addition, errors are ubiquitous in data analysis, and software bugs or misuses are a major contributor to this (Donoho 2010). To take a classic example, a source of error was (and probably still is) the handling of the left versus right hemisphere identification in neuroimaging data, which very likely led to many erroneous publications. Finally, software tools are strongly influencing – and limiting – the type of questions that are put to the data. These factors should place a thorough understanding of one’s analysis software in a predominant place in the research process.

While no neuroimaging research would be done without software, few articles are dedicated to the description of their development and capability. Partly, this is due to the nature of the software description that does not lend itself very well to a static written description; this is better seen through example of use and documentation. Partly, this reflects the somewhat distorted nature of the publication process in neuroimaging (as well as in other scientific fields) that puts too much emphasis on the interpretation (the “story”) and less on the facts (and, inherent to the scientific process, how these were obtained). Donoho famously paraphrased Claerbout ([https://en.](https://en.wikipedia.org/wiki/Jon_Claerbout)

[wikipedia.org/wiki/Jon_Claerbout](https://en.wikipedia.org/wiki/Jon_Claerbout)) stating that *“an article about computational science in a scientific publication is not the scholarship itself, it’s merely scholarship advertisement. The actual scholarship is the complete software development environment and the complete set of instructions which generated the figures”* (Donoho et al. 2009). There is little doubt that neuroimaging is a computational science and that Donoho and Claerbout’s point applies to our field.

In this encyclopedia entry, we lay out the neuroimaging software analysis landscape in section “Detailed Description,” then consider the problems we face currently in section “3,” and suggest directions for solutions in section “4.” We last review some of the future challenges in this field. There will be no attempt to make an even non-exhaustive list of the software currently in use in neuroimaging although we cite some software to illustrate our text. Our purpose is to reflect and inform on some sociological aspects of the brain imaging field related to data analysis software which are likely less ephemeral than current software. We will use examples that are related to the research community from MRI (magnetic resonance imaging) and more rarely EEG-MEG (electro- and magnetoencephalography), but most of the ideas can be extrapolated to other brain imaging modalities (positron-emission tomography, near-infrared spectroscopy, etc.).

Emergence Mechanisms and Taxonomy

We start by reviewing a few mechanisms by which neuroimaging software emerge. We take a few examples to illustrate these mechanisms and then propose a few major criteria for software classification.

Emergence Mechanisms

A Data Analysis Method Developed in a Lab This mechanism is simple and often observed. A good method to analyze data has been developed in a lab and has produced interesting results and led to (possibly high-profile) publications. Other researchers in the same lab, or in other labs, would like to use the same

technique, but it is not easily recoded because of its mathematical or algorithmic complexity. There is a pressure to share the software with colleagues attracted by the technique, as well as reward since ensuing collaborations will lead to authorship for the developer. More rarely, the author believes that scientific work requires that colleagues can check and reproduce one's work. The software may get used locally for a while and then distributed under more or less lenient terms of use and license.

This mechanism is close to what happens for SPM, for instance, started by Karl Friston (Ashburner 2012). SPM is an interesting example because of its predominance in positron-emission tomography and functional magnetic resonance imaging data analysis for a long time. The early distribution of the code, the fact that the software was solving for both spatial normalization and the multiple comparison statistical aspects, and the use of a high-level language (Matlab) were key aspects of its success. To some degree, this is also the story of software such as Brainstorm, MLE, fieldtrip, or others in the EEG-MEG field (see the special issue of Baillet et al. 2011).

The Methodological Lab Development Receptacle More a communal than a single researcher enterprise, laboratories which are mainly dedicated to developing methods are almost systematically developing the software tools to consolidate their research. This often takes the form of a software library, maintained so that research work can build on the previous methods without having to restart coding from scratch with every new student. But many groups have also developed full-fledged applications to demonstrate their research to a wider, more application-oriented community. For instance, the Oxford group, led by S. Smith, was predominantly developing methods to analyze MRI and fMRI data and developed FLS (Jenkinson et al. 2012) to propose an alternative to SPM. It took a few years for the software to establish itself as a valid alternative, but key methodological components and a coding language that did not require buying a license (Matlab can be a significant

budget for a lab) and led to faster execution were important aspects of the initial success. Later, FSL developed methods in diffusion imaging, while SPM developed the “Dynamical Causal Models” techniques, differentiating the two software suites for some applications. Many other examples can be found, such as the Montreal Neurological Institute (MNI) Brain Imaging Center (MNI Software Tools n.d.).

The Commercial Enterprise The transformation of a research software to a commercial product is not an easy enterprise, given the competition of freely available tools. BrainVoyager (Goebel 1996) is a remarkable example of success in this category. The incentive here is clearly to generate revenues, as well as having the means to easily incorporate a new method in one's preferred and controlled environment. BrainVoyager has in particular good visualization components as well as an interface adapted to end users which made for some of its success. More commercial software are used for EEG because of its strong link to the medical community (e.g., Besa <http://www.besa.de>).

Software Evolution Most software platforms that have been around for numerous years undergo an evolution in the set of functions that they perform. SPM started in support of PET imaging and evolved to handle functional and anatomical MRI, EEG, and MEG and more over the years. FreeSurfer (Fischl 2012) initially handles cortical surface extraction and quantification and evolved to include intersubject registration and subcortical segmentation, as well as adapt to numerous cortical parcellations schemes. These developments clearly follow the laboratories scientific directions, but students who are responsible for developing part of the code eventually leave the laboratories and this often lead to code base difficult to refactor and maintain.

One key for the success of all these tools is they are developed by or closely associated with a neuroscience/brain imaging laboratory that publicize the software through publications, talks, or teaching.

What's the Difference? Taxonomy of Software

While criteria for classifications are numerous and often nonindependent, we briefly review four possible criteria.

Application Domain and Scope This is probably the clearest and easiest of these criteria. Eight large categories dominate: (i) anatomical structures, (ii) diffusion imaging, (iii) functional (time-domain) data (PET or fMRI), (iv) electric and magnetic encephalography, (v) visualization tools, (vi) infrastructure software such as pipelining and databasing systems, and (vii) other more specialized software such as imaging genetics, PET modeling, etc. Many of the most used neuroimaging packages include several components, for instance, some visualization aspects and some scripting or pipelining capabilities. Other categories continue to emerge, such as the software for the connectome (e.g., Gray 2011) or “brain reading” (e.g., MVP <http://www.pympva.org/>).

Intended Users Part of the neuroimaging community has trained in psychology, neuroscience, or medicine; others may be trained in computer science, physics, or statistics. Some of software are clearly targeting the former part of the community (e.g., Toussaint et al. 2007), with easy installation and graphical interfaces, while others are at the stage of libraries and require programming skills to be used (e.g., the nipy suites: www.nipy.org).

Code Openness and Licensing These aspects are also critical for adoption in particular by method-oriented researchers. Many of the research software are open source with GPL-/BSD-/MIT-/CECIL-like licenses (e.g., SPM, many of the MEG tools such as Brainstorm or MNE, Baillet et al. 2011). While the code may be open, only a few however have open-source developing modes, where contributors propose changes through the mechanism of “pull requests” and decisions on whether to include or not a change are discussed on mailing lists. Some have licenses that distinguish the commercial and academic uses such as FSL.

Licensing of software remains a problematic in terms of the proliferation of different licensing terms. While the development of the Creative Commons suite of selectable options is a great advance, much software has been released prior to the development of that licensing strategy, and a majority of the software has been developed by investigators working at various academic institutions with specific intellectual property that have been felt to require university-specific terms. As an example, the Neuroimaging Informatics Tools and Resources Clearinghouse (NITRC) hosts over 640 neuroimaging resources, and these require the listing of over 120 separate licenses.

Development Language This may not seem a major criterion at first sight for many. However, the readability of the code, its maintainability, and the flexibility with which the code source can be extended and refactored are major aspects for both maintenance and extension of a software platform. A strong attractive aspect of SPM is that it is written in Matlab, a high-level language that is particularly well suited for matrix algebra, which is at the heart of many of the data analysis methods. This makes it possible for a neuroscientist to adapt the code to develop his or her own ideas. Other high-level languages of the kind are Octave (Matlab clone), Python, and R.

The Problems with Software

There are a number of issues that are associated with the current state of brain imaging regarding software for data analysis. We list below these issues from the most practical to the most general/sociological aspects.

Proliferation: Finding the Right Software

The proliferation of myriad software solutions poses a number of practical issues that researchers or practitioners have to face. As an image processing need becomes more mature, more software has been developed to attempt to deal with it, and the user tends to be faced with more options about how to solve this task in their ongoing studies. Let us take individual image registration to a template image to illustrate this. In 1990, you either wrote the software yourself or accessed AIR

(Woods et al. 1992); today, there are over 10 (AIR, FSL (FLIRT, FNIRT), DRAMS (Ou et al. 2011), SPM-LDDMM, ANTS (Avants et al. 2010), Civet (Ad-Dab'bagh et al. 2006), nipy (nipy.org)) different major software solutions to such a task, spanning linear and nonlinear techniques, varying registration cost functions and different degrees of freedom in the fit, etc. (Klein et al. 2009). Where there are multiple “major” software options, you can be sure that there are many more options that have been developed that you just might not know about. This is not limited to the registration problem. For instance, fMRI had more than two decades to investigate various ways of extracting neuroscience or clinical results from data. To name a few, with fMRI, one can work on the cortical surface or on the volume data and apply dozens of preprocessing steps; MEG data can be analyzed using coherency or with evoked potential and led to many tools (Baillet et al. 2011), in diffusion imaging one can extract individual fibers or work with probabilistic models, etc. The complexity is exponentially increasing when data are combined. To add to the issue, software are constantly evolving, augmented with new functionality and debugged.

While the neuroimaging community may already be facing too many choices, the computer science and engineering literature are rife with algorithms and techniques that just are not commonly investigated by most neuroscience researchers. The main reason is that making these algorithms available to a wide audience requires software development skills that are not always available in methodological research teams. The “cost” to develop, distribute, and maintain a large or complex code and user base software is typically high, although underestimated in the research community.

Given multiple options to choose from, how does the investigator find all the options and choose the best option? Equally importantly, what are the practical differences between the different options?

There are many metrics and proxy metrics for “best” software solution for a given task. Ideally, one would like to know that the software is validated and that it produces the “correct” answer in

testing on when the solution is known. This can include simulation data. However simulation data when computationally known “ground truth” is designed into the data very often cannot mimic complete set of nuances of real data. Similarly, the performance of software under different input conditions (signal to noise ratio, contrast to noise ratio, etc.) is an important characteristic. Traditionally, patient and extreme populations are susceptible to more artifacts (motion) than healthy controls, so how well software performs in the presence of some degree of acquisition imperfections is also critical. It is not uncommon to find that the “best” software in perfect conditions may not be the “best” under more practical, real-world scenarios. Software that is designed and deployed with unit testing and that has been validated and profiled relative to all the available software options is to be preferred.

Popularity is a common criterion for selection of the “best” software option for a researcher. The argument is simple: reviewers will not – or rarely – question a method that has been used in published literature. Similarly, many research laboratories have developed a “culture” of using specific platforms; that’s what the current personnel are used to using, so that’s what they pass on to new investigators. Legacy of analyses performed in a specific way can span decades. Popularity can be quantitatively assessed by metrics like download count and number of publications. However, *popularity, correctness, and usefulness are notions that are far from being fully aligned.*

A last important factor is the documentation and available help with the software. All major software have forums and diffusion lists that often are critical for solving a particular question.

Software Testing

Testing whether the outcome of software is producing the right result is no simple task. This is particularly true for software that offer a high-level graphical interface to the user. One specific issue is that there is yet a lack of quality checking tools embedded in the software most commonly used, such that if, for some reason, part of the analysis fails (entry error, implementation bug or

not covering the use case, etc.), it is hard to find if anything went wrong at all, especially if the results “look” all right. One reason for this, in fMRI, is that although the field has more than twenty years of experience, almost any pattern of activity can be explained in a cognitive task.

At the implementation levels, although the outcome of example dataset or simulations is generally checked to provide reasonable results, the software rarely implement unit and integration testing procedure. This makes the code base fragile to any change. There are famous example of bugs in neuroimaging, and one of the most confusing and leading to a large number of erroneous publications was the left versus right issue (neurological vs. radiological display) as some early image formats did not allow code properly for this information. This was corrected in the NIfTI format (as long as the DICOM to NIfTI conversion is correct – which is not a small assumption). Other examples exist where software has implemented an incorrect statistical correction technique, for instance. Until a more careful and principled approach is taken by the developers of neuroimaging software, we are unclear on the error rate. Note that many of the mistakes may not be due to a specific faulty routine or method, but done during collecting and formatting all the auxiliary information (response time, paradigm sequence, etc.) necessary to launch an analysis. The example of the Duke University scandal (and other such examples) should be kept vivid in the mind of the research community, not as an exception but as a situation that can easily occur (Baggerly and Coombes 2009).

Analyses Reproducibility

A critical aspect to neuroimaging analysis lies in their reproducibility. This is a software issue in the sense that some software platforms will make it almost impossible to reproduce an analysis, for instance, when there is no other option than clicking on graphical interfaces, and detailed graphical logging options are not available. Many software platforms, however, do provide some solutions to this with the ability to script the analysis. This is of utmost importance. The

mechanism is simple: if it takes a few days to set up and run an analysis, and if the results “look all right,” there will be a very strong resistance to start over again in case of doubt. This will also prevent experimentators from checking that results are similar with trivial change of parameters. For instance, if changing a filter value by a small amount changes very significantly the results, these results are not robust, and unless there is a clear way to choose this filter value, the scientific community should not trust the findings. Interestingly, this ability also provides scientists with a way of trying out many filter values and selecting the best results, which poses some other issues addressed later in this entry.

Provenance

Even when scriptable, very few software platforms track and report their complete provenance of operation and attach it to the derived data; and those that do, do not necessarily do it in a standard fashion. First, this is important when software goes through major revisions and the nature of the results and methods can evolve substantially. When it comes to comparing the resultant data with other results, even from the same software system, version information (and computer operating system) can influence the results (Gronenschild et al. 2012). Second, when there is doubt on how the data have been generated within a lab, since there is no way to check their provenance, the only solution is to regenerate the results. This happens relatively frequently when a new student or postdoctoral fellow has to work on previously analyzed data. A third point is that if provenance data existed and were included in the supplementary material or better available digitally, reviewers could check the validity of the computations described in articles.

Data Management and Sharing Capacity

Just as shared raw imaging data is becoming increasingly important, so is the sharing of derived results. Most software do not integrate data management and sharing capacity. This prevents researchers to easily collaborate and build on the work of each other with more direct and effective ways than with the publications. The

data organization impacts in part of the effectiveness (and therefore lower cost) of the research performed and in part the rate of error and provenance tracking capacity.

One of the factors that make raw data sharing work is the existence of standards for data description. Image data formats, such as DICOM and NIfTI, are understood by scanner manufacturers and analysis software platforms alike. When it comes to the derived data however, there is yet neither the culture nor the infrastructure (standards or repositories) to promote widespread sharing of derived data. Standards for the representations of common derived results need to be adopted by a broad set of software developers and derived databases in order to fully promote the sharing of derived data.

Software Installation and Interoperability

A final factor that integrates a number of the aforementioned issues relates to promotion and “marketing” of a software system. There is little incentive and mechanisms so far in the community to establish and use a standard application program interface (API) to help software interact easily. *This is because software are rarely developed across laboratories.* Developers have therefore little interest at easing the interactions with other software and often tend to promote their tools even when it is demonstrated that other solutions may lead to better results. As a number of software packages become more mature, and the development and support infrastructure behind them becomes more complex and expensive, the need to develop continued funding to support the infrastructure is magnified. A laboratory may choose to continue developing some software to have some internal cohesion, or because large resources have been invested (“too big to fail”) despite evidence that more adequate solutions exist or more useful scientific results may be obtained with other software. This points to the immaturity of the scientific community which can act in a competing and individualistic mode when efficiency would require collaboration.

A second aspect is that it can be expected that significant improvements in processing methods have been developed by smaller, more transient software efforts, but it can be very hard to compete

with the established providers to distribute the method. This is because groups controlling which methods are to be integrated in most popular software are also the ones developing methods. There will be a strong resistance to implement a “competing” method in an in-house software. Methodological improvements that are embraced by the field may become adopted and incorporated into the major developers’ packages eventually, but these improved methods have to reach a level of adoption that is not easy to obtain given the established tools.

This may be less the case when software are the products of large consortiums (for instance, from the BIRN, INCF, etc.), often also working on standardization of formats or meta-information. Pipelining systems such as nipype are to some extent breaking these barriers, but they require good knowledge of the pipelining system as well as of the individual software.

Solutions

Some solutions to the issues listed in the previous section are emerging in the neuroimaging community. We list the ones that seem most promising.

Neuroimaging Informatics Tools and Resources Clearinghouse

The host of “problems” introduced above is not new or specific to the neuroimaging software community, and “solutions” to many of them are in place. One important tool in the handling of a rich and diverse set software options is an independent “clearinghouse” of information about all of the software relevant to a particular field. As a clearinghouse, such a resource supports the needs of the software developers to make consumers aware of their software’s availability and supports the needs of users to be able to find all the potential software solutions to a particular problem. For the neuroimaging community, such a resource exists in the Neuroimaging Informatics Tools and Resources Clearinghouse (NITRC – nitrc.org). Funded by the National Institutes of Health Blueprint for Neuroscience Research in 2006, the Neuroimaging Informatics Tools and Resources Clearinghouse (NITRC) is the go-to website for neuroinformatics

software, tools, data, and other resources for an ever-broadening set of imaging domains (Kennedy et al. 2009). Starting with structural and functional MRI, NITRC catalogs virtually every resource in the domain to promote discovery and dissemination. The scope of resources covered by NITRC has expanded to include EEG/MEG/eCoG, PET/SPECT, CT, optical imaging tools, and, most recently, imaging genomics and clinical informatics. NITRC provides three types of services: NITRC Resources Repository (NITRC-R), the collaboration environment hub that enables the distribution, enhancement, and adoption of neuroimaging tools and resources (Luo and Kennedy 2009); NITRC Image Repository (NITRC-IR), a curated repository (developed from the XNAT open-source framework, Marcus et al. 2007) of NIfTI-1 and DICOM images searchable by metadata such as handedness, gender, and group; and NITRC Computational Environment (NITRC-CE) and NITRC-CE for Cluster Compute Instances, virtual big-data compute services (using the Amazon EC2 (Amazon. Amazon Elastic Compute Cloud (EC2) n.d.) Cloud and NeuroDebian, Hanke and Halchenko 2011; Halchenko and Hanke 2012) pre-configured with popular neuroimaging software analysis tools using pay-as-you-go compute time on AWS (Amazon. Amazon Web Service (AWS) n.d.) Marketplace.

In addition, as an independent clearinghouse, all providers, commercial and academic, large and small, and mature and in development, can have exposure to the community. NITRC provides a forum where community dialog about best practices, optimal solutions, standards development, etc., can occur in a fashion that transcends the forums and resources of the myriad individual resource providers. As a data host with community engagement, test datasets can be hosted and standard validation and comparison protocols can be run, and dissemination of the comparative results supported.

The International Neuroinformatics Coordinating Facility

The International Neuroinformatics Coordinating Facility (INCF) develops collaborative neuroinformatics infrastructure and promotes the

sharing of data and computing resources to the international research community. The INCF achieves its mission, in part, through the conduct of “Scientific Programs,” which are long-term strategic undertakings to address issues of high importance to the neuroscience community. Each program provides tools for integrating research findings from different labs and multiple experimental techniques. One of these, the **Standards for Data Sharing** program, aims to develop generic standards and tools to facilitate the recording, sharing, and reporting of neuroscience metadata, in order to improve practices for the archiving and sharing of neuroscience data. Metadata define the methods and conditions of data acquisition and subsequent analytical processing. Within data sharing broadly is the NeuroImaging Data SHaring (NI-DASH) task force. NI-DASH focuses on neuroimaging as a testbed for the development of specific tools and standards for data sharing within neuroimaging (Poline et al. 2012).

Along with the development of standards, INCF supports a number of data repositories designed to promote the adoption of the standards as they are developed. INCF XNAT is a neuroimaging archive that is supported by easy-to-use data sharing tools integrated with the delivery of quantitative feedback quality assurance measures to incentivize image data sharing. INCF Dataspace enables the collaboration between researchers through the sharing of a broad set of neuroscience data, including text, images, sounds, movies, models, and simulations.

Open Science and Open-Source Software Development

Open-source collaborative projects have proved that they can lead to very successful software and be major components in research or industry. Mozilla Firefox, LibreOffice, the Linux operating system, major databasing, and communication systems such as MySQL, PostgreSQL, Apache, etc., are only but a few examples of this. The software are developed by large distributed communities, with core team often scattered around the globe. They have along the years developed the tools and the know-how (the cultural rules) to

interact remotely and make the software evolve. They sometimes attract hundreds of developers whose interest may lie in the product itself, or sometimes just in being part of a community that produces useful software (see Raymond 1999 for a description of the open-source development history process).

Can neuroimaging software adopt this model? Contradicting the Betteridge's law (http://en.wikipedia.org/wiki/Betteridge's_law_of_head_lines), we believe that the answer is yes. An interesting example of this is the nipy libraries suite. Nipy started in Montreal with J. Taylor and then in France and in California (www.nipy.org) at the university of Berkeley and at Neurospin and was originally a library for functional MRI statistical analysis. Early on, the main developer (M. Brett) decided to apply the open-source development principles and constructed an adapted environment, using the most efficient collaborative tools (i.e., the git control version system, the github social coding platform, the python language, a suite of unit test with good coverage of the code base, a nightly building of the software, etc.). Although nipy itself has not made it the large brain imaging community, these working principles have fostered the emergence of multiple useful software projects (nibabel, nipy, dipy, nitime, etc.), and other solid projects are following the same principles (scikit-learn/nilearn, MNE, etc.).

Similarly, at the level of applications, a number of open science and software projects are modeled under the principles of open collaboration, meaning that any developer can propose code changes and the major direction of the software are discussed between developers. Neurosynth, Brainspell, and Neurovault are just a few of promising examples.

The New Challenges

The Reproducibility Problem

Neuroimaging is at a critical point in its sociological development. There are a few critical factors for this. First, many studies include a small number of subjects, and therefore the chance that the alternative hypothesis is true is

low even when the statistical test leads to reject the null hypothesis (Button et al. 2012; Ioannidis 2005). In other words, most of the claims are likely to be false because of power issues. Second, there is a strong sociological pressure to publish in the academic environment. It is clear that publication is the main assessment tool for grant attribution and renewal, as well as for granting tenure position. There are, therefore, very few imaging datasets that are acquired and not published, because the flexibility and multiplication of the analyses will almost certainly provide a significant test. The poor state of our knowledge will almost invariably provide a possible explanation for the results. Simmons et al. (2011) assessed a risk of type I error of about 60% if flexible analyses are allowed in psychology. The flexibility of neuroimaging analyses is even larger, alimmented by the publication pressure. Third, mistakes are ubiquitous, even within the most serious and careful individuals and laboratories (e.g., “anatomy of a coding error”; <http://www.russpoldrack.org/2013/02/anatomy-of-coding-error.html>). In this later case, the author provided a great service to the community in presenting the issue.

By combining these three factors, we conclude that there is a very high chance that many neuroimaging results (or neuroimaging genetics) are likely to be false. Clearly some results are reproduced, and meta-analyses are able to extract common results that are likely to be correct and will be found again. But extracting the solid results with large enough sample size – e.g., having the “big enough” data – or replicating across enough studies close enough in their goal remains a critical challenge of this field, and we suspect of others (see, for instance, an example in cancer research by Begley and Ellis 2012). From the above, we clearly see that neuroimaging has not been well served by our current publication paradigm. If one is interested in a result published in a journal, it is most often impossible to replicate the results, assess its validity, and link it to results of the same kind. The result – and the knowledge that we can extract from it – is in effect a sentence in a pdf file. Tools to mine text are being developed – but tools to link the scientific claim to the

data and computation that have led to the claims are mostly to be developed.

The field needs to generate a framework for deploying reproducible and re-executable neuroimage processing workflows to support the full connection between data, processing, results, and published claims so that the inference can persist and be dynamically assessed as the available data evolves over time. In addition to simply being able to re-execute a specifically published analysis (which by itself is significant and important), this will enable vastly new ways of querying data and performing analyses. One can take a publication perspective and from a result in one publication discover other publications that used similar data, found a similar finding, or used a similar analysis method. One can then explore all the parameters of an experiment. The primary authors of a paper may not be able to probe or explore all experimental factors, nor should they; but that does not mean that the stability of results relative to parameter settings, other data sources, is not important to explore. We cannot continue to assume that the one published set of observations from a particular set of data is the only interpretation. This “dynamic” nature needs to be exposed, so that all experimental parameters can be part of the ongoing dialog about what a set of observations mean and how they extend as the data available changes.

Computational Challenges

Virtualization Software deployment and utilization, for both the developer and user, is hampered by the proliferation of operating systems and hardware platforms. This places extra demands on developers to support the many platforms their users may be using and on users to deal with many software installation dependencies that may or may not be compatible with their existing hardware platform. This proliferation of platforms leads to increased variance in the results and provenance of ongoing neuroimaging studies and limiting data integration and aggregation. One major effort designed to alleviate some of these issues is NeuroDebian. The NeuroDebian project (<http://neuro.debian.net>; Halchenko and Hanke

2012) integrates many neuroimaging (and generic computing and neuroscience) software developments in a turnkey platform. Besides preparing, testing, and uploading software for inclusion into official Debian GNU/Linux distribution immediately making those available to millions of users worldwide, NeuroDebian project provides a repository with backport builds of maintained software for all supported Debian and Ubuntu releases making them available on top of existing deployments of their stable and LTS releases. NeuroDebian virtual appliance provides users of other platforms (e.g., Windows or OS X) a seamless solution for deploying complex analysis environments for research, teaching, and collaboration. Integration of software within a uniform software and data deployment platform allows for a seamless installation and maintenance of computing environments staying at the frontier of methodological developments while also allowing for easy instrumentation of existing installations on bare metal, or automated Debian-based deployments locally (VirtualBox <https://virtualbox.org/> and Vagrant <http://www.vagrantup.com/> or Docker <http://www.docker.io/>), or cloud appliances.

Distributed Computation There is still a long way to go in the initiative to enable a comprehensive data sharing infrastructure for the neuroimaging community. Nevertheless, numerous successes in large-scale image data sharing have occurred (i.e., Alzheimer’s Disease Neuroimaging Initiative (Mueller et al. 2005), National Database for Autism Research (Hall et al. 2012), Autism Brain Data Exchange (Di Martino et al. 2013), 1000 Functional Connections (Biswal et al. 2010), INDI http://fcon_1000.projects.nitrc.org/indi/IndiPro.html; Mennes et al. 2013; The ADHD-200 Consortium 2012, etc.). This means that researchers now have access to thousands of publically available neuroimaging cases. This blessing of data is matched with a curse of computation. As the available data grows and the complexities of processing and pooling data in specific domains increase, the demands on the availability of high-performance or large-scale computational resources skyrocket. The era of imaging analysis requiring processing workflows

that operate on thousands of cases is upon us. While many universities are fortunate enough to host local high-performance computational resources, not all investigators have access to such computational resources, and even those that do may or may not have these configured to handle the necessary neuroimaging processing software tools. In addition to local high-performance computing, the emergence of consumer-accessible cloud computing has brought the availability of scalable, on-demand computing to the community. Relatively simple configure of local and cloud-based neuroimaging systems is now easily deployed using such resources as NeuroDebian, VirtualBox, NITRC Computational Environment, and StarCluster. Thus, the acquisition of massive amounts of compute nodes is no longer rate limiting.

More limiting, at the moment, is the logistics and expense of moving the vast data resources to the processors. Now that net input data volumes to the workflows can be on the order of Terabytes, moving (or copying) this data to a local computer system will be intolerably slow (as well as relatively insecure). As data sources begin to reside on cloud-based storage facilities, and mirrored to multiple national and international sites, the financial and temporal pressures to move the computational processing to the cloud “nearby” will increase dramatically. This will usher in a completely new era in the design and financing of modern large-scale neuroimaging computational analysis.

Training and Collaboration As the world of neuroimaging data analysis and software development complexifies, the need for training the new generations of researchers to the new collaborative tools is becoming clear. None will be able to be an expert in all the domains required by brain imaging (image acquisition physics, applied mathematics and statistics for data analysis, software development, and the application field of neuroscience, cognitive neuroscience, neurology, or psychiatry). The only practical solution is to train on how to collaborate efficiently between individuals with complementary expertise. This means learning the common language of

collaboration through Internet, such as version control systems and collaborative development tools. As neuroimaging has become a computational field, we need to respond to the new challenge of training researchers on how to collaborate on computational projects, as well as clarify how acknowledgments and credits are to be handled in groups of individuals originating from multiple institutions and countries. The new “brain imaging” curriculum should have a significant component on this as this critically impacts both the quality and the efficiency of the research performed.

Conclusion

The neuroimaging research community could gain both in efficiency and in correctness by focusing more on its basic tools. In the same way that a common image format facilitates greatly the adoption and use of software tools, common application program interfaces, provenance exchange formats standards, test datasets, and community platforms, linking data to publications and programming training would lead neuroimaging to another level of efficiency. This may have to be the tasks of an emerging research field: the brain imaging neuroinformatics – or brain informatics.

Somatosensory Cortex: Neural Coding of Motion

Yu-Cheng Pei

Chang Gung Memorial Hospital and University,
Taoyuan City, Taiwan

Synonyms

[Aperture problem](#); [Tactile motion](#); [Tactile motion integration](#)

Definition

The tactile perception of motion involves the perception of movement of an object across the skin. Neural processing in the somatosensory cortex transforms the information originating from populations of afferents into a percept of the direction and speed of the tactile motion.

Detailed Description

Two Sources of Tactile Motion Information

The perception of tactile motion is thought to rely on two types of signals at the somatosensory periphery: the sequential activation of slowly adapting type 1 (SA1) (Johansson and Vallbo 1979) and rapidly adapting (RA) afferents (Kirman 1974; Sherrick and Rogers 1966) as an object moves across the skin and the activation of slowly adapting type 2 (SA2) afferents (Olausson et al. 2000) caused by friction-

induced skin stretch resulting from motion (Olausson and Norrsell 1993).

Direction Tuning Emerged in the Primary Somatosensory Cortex

SA1 and RA afferents encode stimulus motion in a pixel-wise manner, and each single afferent exhibits little to no direction tuning (Whitsel et al. 1972; Pei et al. 2010); that is, the responses of these afferents are not modulated by the direction in which an object moves across their receptive field. Direction tuning emerges in primary somatosensory cortex (S1), namely, in areas 3b, 1, and 2 (Werner and Whitsel 1970; Whitsel et al. 1972; Costanzo and Gardner 1980; Warren et al. 1986; Ruiz et al. 1995). The direction tuning of S1 neurons has been hypothesized to be shaped by asymmetrical lateral inhibition in a feedforward neural circuit (Gardner and Costanzo 1980). Specifically, a cortical neuron receives inputs from subcortical neurons with adjacent receptive fields, and each input suppresses the input from an adjacent spatial location. If inhibition along one direction is stronger than along the opposite direction, the neuron would exhibit direction tuning.

Neurons in Primary Somatosensory Cortex Exhibit Shape-Invariant Direction Tuning

The preferred direction (*PD*) of neurons in S1 is invariant across stimulus types (including bars, dot patterns, and random dot displays), amplitudes, and motion speed (Fig. 1) (Pei et al. 2010). That is, they respond most strongly to motion across the skin in a given direction, regardless of the geometric properties of the object scanned across the skin. While neurons in area 3b exhibit some direction tuning, neurons in area 1, which is downstream to area 3b, produce responses that are more strongly dependent on motion direction. The responses of area 1 are highly predictive of the perceived direction of motion, suggesting that this population of neurons plays a causal role in tactile motion perception.

Motion Integration Is Mediated by a Terminator-Mediated Vector Average Model

Plaids, which are constructed by superimposing two moving gratings (Pei et al. 2008), can be

Somatosensory Cortex: Neural Coding of Motion, Fig. 1 Responses of a neuron in area 1 to bars (a), dot patterns (b), and random dot displays (c) presented to the monkey's fingertip. The stimuli are illustrated as insets at the top: for bars and dot patterns, the *white square* shows the 1 × 1 cm area at which the stimuli were presented; the *gray region* illustrates the stimulus extending outside of the stimulation area. To the left of each raster is the direction of

motion of the stimulus. This neuron produced the most robust response to stimuli moving from left to right (with a slight slant outward), regardless of whether the stimuli were bars, dot patterns, or random dot displays. For random dot displays, the tuning response increased with increases in the motion coherence. *Error bars* denote mean ± s.e.m. (Reproduced from Pei et al. (2010) with permission from PLoS Biology (Pei et al. 2010))

used to understand how motion information is integrated across the sensory sheet. Based on the responses to these more complex stimuli, a model for tactile motion integration was developed that predicts both neuronal responses to and the perception of tactile motion across a variety of conditions (Pei et al. 2011). According to the model, the representation of motion is determined by the motion vectors of the component gratings, as well by the intersections of the gratings (which constitute terminators, whose motion direction is unambiguous). Components and terminators are then weighted according to their speeds and amplitudes

account for the *PDs* and combined using a vector average (Fig. 2).

Processing of Motion Speed in the Primary Somatosensory Cortex

Human subjects can scale the perceived speed of tactile motion stimuli (Essick et al. 1988; Bensmaia et al. 2006). The structure of scanned objects is essential for tactile speed perception as evidenced by the fact that speed information is unavailable for smooth surfaces (Depeault et al. 2008). Furthermore, the spatial characteristics of the surfaces – i.e., their texture – influence speed perception. A population of neurons in areas 1 and

Somatosensory Cortex: Neural Coding of Motion, Fig. 2 A terminator-mediated vector average model for tactile motion integration. (a) Breakdown of the stimulus features for input components into the VA model. Green and blue contours and arrows correspond to the component edges and their respective directions of motion; red vertices and arrows correspond to the terminators and their

direction of motion. (b) Computation for the stimulus direction based on the direction of its components. Each feature is weighted according to its density (length of the edges, density of the terminators), its amplitude, and its speed. Weighted unit direction vectors are then summed to compute the perceived direction. (Reproduced from Pei et al. (2011) with permission from Neuron (Pei et al. 2011))

2 exhibit a graded increase in discharge with increasing speed, and their responses are affected by spatial period, suggesting a role in tactile speed scaling (Depeault et al. 2013).

Somatosensory Cortex: Neural Coding of Shape

Jeffrey M. Yau

Johns Hopkins University, Baltimore, MD, USA

Definition

We appreciate object shape information by touch alone. Spatial feature representations, initially carried by populations of slowly adapting type I afferents (SAIs) in the peripheral nervous system, are centrally encoded by neural populations residing in the somatosensory cortex. Cortical neurons function as spatial filters that select out

specific object features falling within their receptive fields (RFs) on the skin. This neural selectivity, or tuning, changes across a hierarchy of processing stages spanning primary (S1) and secondary somatosensory (S2) cortices (Fig. 1a). While somatosensory neurons at the first cortical processing stage (area 3b in S1) have small receptive fields and respond to simple contour features like oriented bars and edges, neurons at intermediate and later processing stages (area 2 and S2) respond to stimulation of larger skin regions and are selective for more complex spatial features. In individual neurons and across neural populations, spatial tuning evolves in time, reflecting extensive and rapid network processing. Decoding of object shape information requires integrating activity over neural populations tuned for cutaneous and proprioceptive information.

Detailed Description

We rely on our sense of touch to perceive and manipulate objects. Consider the act of holding a smartphone in one hand (Fig. 1b) – although much of the phone’s body is cradled in the palm of your hand, notice how your fingers are deftly positioned around the phone’s frame, allowing you to grip it easily and securely. If you gently adjust and tighten your grip, you may notice how the phone’s frame presses into each individual finger, and you can focus your attention on how the frame passes over your skin along a single edge (Fig. 1b, red dashed line). Shape perception is based in part on this cutaneous information, and importantly, regardless of where your fingers and thumb fall on the phone as you adjust your grip, you maintain a stable perception of the object in your hand. This stable object representation is encoded in the distributed neural activity over shape-sensitive neurons in the somatosensory cortex.

To understand how shape information is represented in the brain, we must consider how this information is initially encoded at the hand. Specialized mechanoreceptors in the skin respond to different cutaneous aspects of object contact

**Somatosensory Cortex:
Neural Coding of Shape,**

Fig. 1 Somatosensory system and shape perception. **(a)** The somatosensory cortical system in primates comprises primary (S1) and secondary (S2) somatosensory cortices. S1 consists of a densely interconnected set of regions: Brodmann areas 1, 2, and 3. **(b)** Tactile shape perception requires the integration of cutaneous and proprioceptive information. The phone's straight edge (red dashed line) is processed within each finger pad and is represented as an oriented edge feature in the activity of cortical neurons

(Johnson 2001). Note that separate afferent populations also carry proprioceptive information about hand conformation, which is necessary for stereognosis (i.e., haptic perception of objects) – this information is integrated with cutaneous shape information in the cortex (see below). Individual afferents display no spatial tuning and only respond when a stimulus impinges the afferent’s small RF. In this manner, a shape’s spatial profile is carried in the total activity over a population of afferents. Of the cutaneous afferents, SA1 fibers carry the most refined spatial information, and the SA1 population activity conveys a low-pass filtered neural image of a tactile stimulus that is isomorphic with respect to the contacted shape. Ultimately, information about object shape must be extracted from a pattern of activation across a two-dimensional sheet of receptors embedded in the skin. The challenge to characterizing somatosensory shape coding, then, is in understanding how cortical neurons process this two-dimensional spatial information conveyed by peripheral afferents.

Spatial Filtering

A large body of neurophysiological evidence implicates area 3b of S1 cortex as the primary cortical recipient of sensory input projecting from the afferent systems, sent via the dorsal column nuclei and the thalamus (Bensmaia and Yau 2011). Area 3b neurons function as linear spatial filters that cover small regions on a single finger pad: A neuron’s RF is a linear approximation of the effects of stimulus elements inside the RF on the neuron’s response. Stimulus contact in any single RF region can result in an increase or decrease in spiking activity, and a neuron’s overall response to each stimulus pattern is given by the sum of the effects of the stimulus elements over all RF regions. This can be formalized as

$$r(t) = b_o + b_1 \cdot 5emx_1(t) + b_2 \cdot 5emx_2(t) + \dots b_ix_i(t) \tag{1}$$

where $r(t)$ is the spiking activity predicted in response to the stimulus pattern at time t , b_0 is

the baseline firing rate, b_i is the effect strength (positive or negative) of a stimulus element in the i th region of the skin, and $x_i(t)$ is the stimulus value in the i th region of the skin (e.g., as in a bitmap, where a value of 1 indicates the presence of a stimulus element and 0 indicates no contact) at time t . The model can be rewritten in matrix form in order to solve for the set of weights defining the linear RF:

$$r = Xb \quad (2)$$

where r is a vector containing firing rates over all response times, X is the stimulus matrix, and b is a vector of weights (plus a constant term) describing the RF. The matrix equation can be solved for b :

$$b = (X^T X)^{-1} X^T r \quad (3)$$

where $X^T X$ is the stimulus autocorrelation matrix (which is an identity matrix when a white noise

stimulus devoid of temporal and spatial correlation is employed). RF maps for cortical neurons recorded from area 3b, derived from linear regression or reverse correlation, display obvious structured organization and typically consist of a central excitatory field flanked by one or more inhibitory fields (DiCarlo et al. 1998).

The shape and arrangement of these RF structures, or kernels, clearly underlie the spatial tuning of area 3b neurons. Specifically, a neuron may respond vigorously to a small bar indented in its RF at a particular orientation, and its response strength will decrease as the bar's orientation deviates from this "preferred" orientation (Fig. 2a). The shape and orientation of the RF structures tend to match that of the "preferred" bar orientation. Because of the clear correspondence between RF composition and spatial selectivity, orientation tuning in area 3b neurons can also be parameterized with two-dimensional Gabor filter RF models (Bensmaia et al. 2008;

Somatosensory Cortex: Neural Coding of Shape, Fig. 2 Neural coding of bar orientation. (a) *Top*: spiking activity of an example somatosensory neuron to a bar stimulus presented briefly within the neuron's RF at different orientations reveals clear response modulation that is consistent over repeated trials (*rows* in the raster plot). *Bottom*: orientation-tuning curve shows the neuron's response as a function of bar orientation and a clear

preference for bars oriented near 67.5°. (b) *Top*: RF map for a different orientation-tuned cortical neuron computed by averaging responses (*scale bar*) to small punctate probes presented at each RF location. *Bottom*: RF map capturing orientation selectivity with a two-dimensional Gabor function (relative response weight for each pixel given by *scale bar*)

Fig. 2b). Although the neural basis for the linear RF composition is unknown, such organization likely results from the patterned convergence of afferent inputs projecting through the medial lemniscal system. However, cortical response selectivity is likely also shaped by recurrent network interactions among cortical populations (see below).

Neural responses become more selective as one ascends the somatosensory processing pathway. As a result, while the responses of afferents and of neurons in area 3b can be accounted for effectively using linear models, the responses of neurons in area 1, the primary recipient of projections from area 3b, cannot. Indeed, neurons in area 1 exhibit many properties that are similar to their counterparts in area 3b (e.g., orientation tuning), but detailed RF comparisons consistently reveal more complex spatial selectivity in area 1. Response properties continue to grow more complex and nonlinear in area 2 (the most caudal S1 region in the postcentral gyrus) and in S2 (located in the superior bank of the lateral sulcus).

RF size increases dramatically to span multiple fingers and even one or both hands in their entirety (in the case of S2 neurons). Linear RF models account for little response variance in most neurons in these populations as shape coding transitions from orientation selectivity to curvature tuning (Yau et al. 2009): Individual neurons respond preferentially to curved and angled contour fragments pointing in narrow direction ranges (Fig. 3). Although these response patterns cannot be approximated with two-dimensional spatial filter models, they can be modeled explicitly with tuning functions in the curvature direction domain. Thus, we can consider transitions in shape coding within the somatosensory system as projections of shape representations from an initial two-dimensional skin-based coordinate space into orientation and curvature feature spaces. Neural computations that transform object information into higher-order contour derivatives (orientation is a first-order spatial derivative; curvature can be defined as the rate of change in orientation along a contour, a second-order

Somatosensory Cortex: Neural Coding of Shape, Fig. 3 Neural coding of contour curvature. (a) Gray scale indicates average spiking activity of a neuron in area 2 responding to contour fragments indented into the skin at different curvature directions. (b) Raster plots and

peri-stimulus time histograms showed curvature responses sorted by direction (rows in a). Central bouquet plot depicts the same neuron's average responses as a function of direction and reveals its strong preference for *leftward* (180°) pointing curves

Somatosensory Cortex: Neural Coding of Shape, Fig. 4 Dynamic spatial response properties. Example spatiotemporal receptive field (STRF) for a peripheral afferent unit (*top*) and a cortical neuron (*bottom*). Pixel color (*scale bar*) indicates response contribution of each RF location

(spikes per second per micrometer). The majority of cortical STRFs in areas 3b and 1 comprise an excitatory center coupled with surround inhibition and trailed by replacing inhibition

derivative) may be especially efficient for building compact and sparse shape representations. In other words, these transformations in shape representations can help minimize the number of active neurons required for coding shape, thereby reducing the metabolic demands related to shape processing.

Position Tolerance

Shape-selective responses in many area 2 and S2 neurons exhibit position consistency: Tuning preferences are maintained even as stimulus features are moved over different RF locations. Although stimulus position changes can result in general response strength modulations, the relative preference for particular ranges of edge orientation or contour curvature direction is preserved regardless of where the stimulus is presented within and across finger pads (Fitzgerald et al. 2006). This position tolerance is computationally demanding and requires nonlinear shape coding mechanisms.

Temporal Dynamics

Shape coding in the somatosensory system is a dynamic process which takes place over tens to hundreds of milliseconds after a stimulus contacts the skin. Dynamic shape coding in the peripheral

afferent system and cortical neurons has been studied by characterizing selectivity using spatiotemporal receptive field (STRF) models, which capture the temporal modulation of neural RFs, in addition to their spatial tuning properties (Fig. 4). (These models are a temporal extension of the spatial filtering models described above.) Cortical neurons display a range of spatiotemporal response patterns, and the most common STRF (in areas 3b and 1) consists of initial excitation, flanked by inhibitory regions (“surround inhibition”) and followed by a long period of (“replacing”) inhibition (Sripati et al. 2006). Because of this composition, the majority of cortical STRFs are space-time inseparable: RFs cannot be decomposed into the product of a spatial kernel (excitatory region) and a temporal kernel (e.g., an exponential response decay or a difference of two exponential decays). (Note that some cortical STRFs lack surround inhibition, like afferent STRFs, making them space-time separable.) Although the neural basis for these dynamic response patterns is still unknown, there is little question that evolution of RF composition depends on rapid intracortical interactions. Importantly, particular aspects of dynamic shape coding, especially the spatiotemporal profile of inhibition, may play a critical role in establishing response properties like invariance to scanning velocity (DiCarlo and Johnson 1999), i.e., a preference for spatial patterns that is consistent across a range of scanning speeds. Moreover, recurrent

network interactions likely also contribute to the dynamic feature selectivity observed in cortical neurons: Orientation selectivity builds gradually in areas 3b and 1, after population spiking activity peaks (Bensmaia et al. 2008), and curvature signaling similarly lags an initial buildup of spiking activity in areas 2 and S2 (Yau et al. 2013). Such response time courses may reflect the role of cortical inhibition in sculpting neural selectivity and sharpening shape representations over time.

Proprioception

Representation of three-dimensional object shape requires the integration of cutaneous and proprioceptive information. Consider again the act of holding and perceiving a smartphone in your hand: All of the cutaneous processing described above only accounts for your ability to perceive the phone's straight and curved boundary edges in contact with your fingers. The exact computation used by somatosensory neurons to combine these cutaneous representations with hand conformation information is unknown, but neuroimaging and neurophysiological evidence implicate neural populations residing in area 2 (Mountcastle 2005). Indeed, area two neurons, while selective for cutaneous stimulus patterns, are additionally sensitive to the three-dimensional arrangement of the hand and fingers (Iwamura and Tanaka 1978). Accordingly, area 2 lesions result in clear haptic object perception deficits (Carlson 1981). There is also evidence that area two responses may be influenced by motor command signals in the context of active object exploration (London and Miller 2013): This proprioceptive feedback (which may be the result of efference copy) from the motor system could serve to gate self-generated sensory signals and to refine shape representations acquired during object manipulations.

Conclusion

Shape representations are carried in population activity of somatosensory cortical neurons. Across different levels of a cortical hierarchy,

shape representations transition from occupying a skin-centered coordinate space to higher-order feature spaces. Response selectivity grows more complex at successively higher processing stages in the somatosensory cortical pathway: Linear responses give way to nonlinear responses. Neural response patterns evolve rapidly in time, reflecting intracortical interactions that sharpen shape representations. In many respects, the principles of shape coding in the somatosensory system resemble those that apply to shape coding in the visual system (although equivalence may be restricted to two-dimensional shape representations). Despite our advancements in understanding neural shape coding in the somatosensory cortex, the computations underlying three-dimensional object representations, which require the integration of cutaneous and proprioceptive information, are not well understood. Similarly, whether and how haptic shape information interacts with other object characteristics like texture and temperature remains to be tested. Finally, the computations underlying the decoding of tactile shape representations for perceptual access and executive functioning remain to be characterized.

Somatosensory Cortex: Organization

Gregg Tabot

Committee on Computational Neuroscience,
Somatosensory Research Lab, University of
Chicago, Chicago, IL, USA

Detailed Description

History

In 1909, Brodmann published maps of the different regions of cortex in humans and monkeys (Brodmann 1909). He partitioned the postcentral gyrus into three distinct areas based on cytoarchitecture and cell organization. From rostral to caudal, he designated these areas as areas 3, 1, and

2. Later studies showed that Brodmann's area 3 could be functionally and structurally divided into two distinct areas now labeled areas 3a and 3b (Vogt and Vogt 1919). Although all four brain areas are often together designated primary somatosensory cortex (S1) and to an extent respond to cutaneous stimulation, area 3b is most analogous to the other primary sensory cortices given its similarity in inputs and laminar structure. Area 3b is thus S1 proper.

Later, in 1940 Adrian discovered a second brain region, adjacent to S1, which contained representations of the forefoot and hindfoot in cats (Adrian 1940). Adrian initially thought this area to be a cortex dedicated to the cats' special ability to extend and retract their claws; however, Woolsey was able to show that this additional somatosensory area, now known as the secondary somatosensory cortex (S2), is shared by monkeys and other animals (Woolsey 1943).

Structural Organization

Area 3a is located in the fundus of the central sulcus, contiguous to primary motor cortex (area 4) on the rostral side and to area 3b on the caudal side. Area 3b lies on the rostral bank of the postcentral gyrus and, proceeding caudally, abuts area 1, located at the apex of the postcentral gyrus, followed by area 2, which lies on the apex and sometimes on the caudal bank of the postcentral gyrus (Fig. 1).

Each of the four brain areas comprises a distinct cortical representation of the contralateral body (Kaas et al. 1979) (Fig. 2). The representation of each body part in the cortex is not proportional to its physical size or mass. Instead, the parts of the body with dense innervations (i.e., the hand or face) have larger cortical representations than do parts that are more sparsely innervated (i.e., the back or leg) and likely contribute to a richer sensory representation.

S2 is located in the parietal operculum on the upper bank and ceiling of the lateral sulcus (Woolsey et al. 1979). The structural organization of S2 is not as well characterized as is that of S1 but is thought to comprise at least two distinct cortical representation of the contralateral body (Krubitzer et al. 1995).

Somatosensory Cortex: Organization, Fig. 1 Primary somatosensory cortex comprises four brain areas: areas 3a, 3b, 1, and 2

Somatosensory Cortex: Organization, Fig. 2 A coronal view of primary somatosensory cortex from a single hemisphere of the brain. The size of the body part represents how much cortical volume is devoted to processing that part

Functional Organization

Area 3a, considered a transitional zone between the motor and somatosensory cortices, receives and processes information about muscle stretch, joint movement, and posture from muscle receptors (Yumiya et al. 1974) and possibly other proprioceptors. Area 3a is thought to contribute to the

sense of proprioception, the awareness of the position, and movements of one's body. Its dense reciprocal connections with motor cortex (Zarzecki et al. 1978) suggest a role in the coordination of movements.

Tactile information is processed in areas 3b, 1, and 2 in a hierarchical fashion (Iwamura 1998). Cutaneous signals are first processed in area 3b (via projections from the ventral posterior nucleus of the thalamus) then are further elaborated in areas 1 and 2 (which also receive some thalamic input) before being sent to S2 or other associative areas for further processing. The hierarchical progression is observed in the increasing latencies of the responses to tactile stimuli (Lebedev and Nelson 1996) and in the response properties of neurons. Indeed, receptive fields (RFs) get larger as one ascends the processing pathway from area 3b to 2, and neurons exhibit increasingly complex response properties as one proceeds caudally (Iwamura et al. 1993), such as a selectivity for direction of motion (Pei et al. 2010) or the orientation of edges (Bensmaia et al. 2008). In addition to exhibiting complex cutaneous RFs, neurons in area 2 also receive proprioceptive input, suggesting that this area mediates the integration of cutaneous and proprioceptive information to achieve a three-dimensional percept of objects.

Cutaneous and proprioceptive neurons from S1 then project to S2, which is functionally divided into different fields: anterior, central, and posterior (Fitzgerald et al. 2004). Neurons in the central field are sensitive to cutaneous stimuli with RFs that often span multiple digits (Krubitzer et al. 1995). Some neurons exhibit orientation selectivity over their (large) RFs (Fitzgerald et al. 2006) and even more complex shape tuning properties such as a selectivity for orientation (Yau et al. 2009). In contrast, neurons in the anterior and posterior fields are more sensitive to proprioceptive stimuli than to cutaneous stimuli (Fitzgerald et al. 2004).

In addition to processing cutaneous and proprioceptive stimuli, both S1 and S2 process noxious stimuli (Treede et al. 1999): S1 neurons seem to encode pain intensity while S2 neurons may be involved in signaling the presence of any pain (Timmermann et al. 2001).

Somatosensory Neurons: Spike-Timing

Hannes Saal

Department of Organismal Biology and Anatomy,
University of Chicago, Chicago, IL, USA

Synonyms

[Entrainment](#), [First-spike latency](#), [Phase-locking](#), [Temporal coding](#)

Definition

A long-standing controversy in neural coding has been about whether the timing of individual action potentials (spikes) conveys information and is behaviorally relevant or whether information is instead transmitted simply by neurons' firing rates. Both peripheral and cortical somatosensory neurons in primates can exhibit precisely timed action potentials in response to tactile stimuli, and there is a growing consensus that not only is some tactile information exclusively represented by such temporal codes but also that spike timing can shape tactile perception.

Detailed Description

Precisely Timed Responses of Cutaneous Mechanoreceptors to Skin Vibrations

In primates, rapidly adapting (RA) and Pacinian (PC) afferents entrain to medium- and high-frequency vibrations, respectively, in that their action potentials occur precisely within a given phase of each stimulus cycle (Talbot et al. 1968). Such precise timing can also be seen in the responses to diharmonic and noise stimuli (Muniak et al. 2007, see Fig. 1). PC responses are generally more precise than RA responses. Slowly adapting type I (SAI) afferents only respond weakly to vibrations, and their spikes are not precisely

timed. Finally, the temporal patterning has been shown to be behaviorally relevant at a fine temporal resolution, by presenting different stimuli that elicit similar or the same firing rates and then test whether those are perceptually discriminable (Mackevicius et al. 2012). One behavior where skin oscillations are especially relevant is texture perception, where RA and PC afferents respond with precise temporal spiking patterns to texture-elicited skin vibrations (Weber et al. 2013).

Peripheral Responses During Object Manipulation

Another temporal code might be active during object manipulation. When grasping an object,

Somatosensory Neurons: Spike-Timing,

Fig. 1 Responses of a PC afferent to sinusoidal, diharmonic, and bandpass noise stimuli. In each of the three panels, the top trace shows the time-varying position of the vibratory stimulus (with the three amplitudes marked to the right). The raster plots show the responses of a PC afferent to five repeated presentations of the stimulus at the three stimulus amplitudes. The bars to the right indicate the spike counts evoked on each stimulus presentation. While spike counts tend to change with stimulus amplitude, temporal patterning in the afferent response is more consistent across amplitudes. (Adapted from Mackevicius et al. (2012))

one needs to rapidly adapt grip forces depending on object properties to prevent slip or over-grasping. Information about object curvature and similar properties is encoded mostly by SA1 and RA afferents. It has been shown that in addition to firing rates, the first-spike latencies of SA1 and RA afferents are highly informative about object features. A neural code based on first-spike latencies could explain how tactile feedback is rapidly integrated into motor commands (grip force adjustments can occur within 100 ms) (Johansson and Birznieks 2004; Saal et al. 2009).

Spike Timing in Somatosensory Cortex

Whether spike timing matters in primate somatosensory cortex is more controversial. It is often assumed that even though peripheral afferents might exhibit precisely timed spikes, such temporal information might be converted into a rate code on the way to cortex. Thus, most work on somatosensory cortical neurons has focused on characterizing the makeup and extent of spatial receptive fields using firing rates. A notable exception concerns flutter stimuli (low-frequency vibrations in the range of 5–50 Hz), in response to which cortical

Somatosensory Neurons: Spike-Timing, Fig. 2 Temporal patterning in cortical responses to sinusoidal stimulation. (a) Autocorrelations (top) and interspike interval histograms (bottom) for one neuron in area 3b, whose responses are entrained with the stimulus up to 800 Hz. (b) Phase histograms along with vector strength (r) for the same neuron as in (a) showing action potentials tended to occur during a restricted phase of each

stimulus cycle. (c) Spectrograms for the same neuron as in (a), with corresponding power spectral densities (PSD) in the insets to the right. Note that the temporal patterning begins almost immediately and lasts for the duration of the stimulus and that the fundamental frequency in the neural response reflects the frequency of the sinusoid. (Adapted from Harvey et al. (2013))

somatosensory neuron both exhibit entrainment (phase-locking) and modulate their firing rates. However, changes in the perception of flutter stimuli align more closely with changes in the firing rates of cortical neurons rather than changes in their temporal profile, which has led to the conclusion that spike timing plays no role in the perception of flutter stimuli (Luna et al. 2005; Salinas et al. 2000). For high-frequency texture-like vibrations, however, a different picture emerges. For such stimuli, their amplitude is signaled in the slowly time-varying firing rates of cortical neurons, while their frequency content is transmitted by precisely timed action potentials (Harvey et al. 2013, see Fig. 2). Such a code is an instance of multiplexing, where different kinds of information are transmitted by different aspects of the neural response. Interestingly, information about amplitude and frequency is separated so well by these two different codes that some frequencies would be impossible to tell apart without, providing a strong argument that spike timing is indeed behaviorally relevant.

Spike Timing and Attention

Spike timing across a population of neurons can also carry information. Specifically, attention modulates the synchrony of spikes of cortical somatosensory neurons (Steinmetz et al. 2000). Such a mechanism might enhance the saliency of attended stimuli by increasing the number of coincident spikes across the neural population.

Detailed Description

Our ability to dexterously manipulate objects relies heavily on somatosensory signals from the hand (Johansson and Flanagan 2009). Receptors

embedded in the skin, joints and muscle convey information about the size, shape, and texture of grasped objects, and signal whether these are slipping from our grasp. The sensory experience of our hand also plays an important role in conferring to it embodiment, making it feel a part of us. Without these signals, using our hand to perform even the most rudimentary tasks would be slow, clumsy, and effortful. Given the importance of somatosensation in natural motor behavior, to achieve a clinically viable upper-limb neuroprosthesis will require that this sense be restored.

Sensory Substitution

There are a variety of approaches to conveying useful somatosensory feedback for use in upper-limb neuroprostheses. The least invasive approach consists of substituting lost sensation by mechanically stimulating – with vibratory motors, e.g., – regions of the sensory sheet that are still intact (the face, for example) (Stepp et al. 2012). In both amputees and individuals with upper spinal cord injury – the two patient populations that are targeted with these technologies – mechanical stimulation can be applied to signal movements of the hand and objects contacting it. While sensory substitution does not require surgical intervention, the patient must learn to associate patterns of skin stimulation with hand movements or with object contact, which may require extensive training. Furthermore, given spatial constraints, patients can only be instrumented with a relatively small number of stimulators, so sensory substitution can be used to convey only limited information compared to the high-bandwidth of the intact native hand.

Neural Interfaces

An alternative approach consists of interfacing directly with the nervous system. Indeed, in intact individuals, signals from the hand are carried via nerve fibers that climb up the arm and the spinal cord before they synapse onto neurons in the brainstem (in the dorsal column nuclei). These

secondary afferents then cross the midline and project to the ventroposterior nucleus thalamus, which in turn projects to primary somatosensory cortex. In principle, an interface can be developed to interact with any of these neuronal populations by developing the right type of implantable device (Weber et al. 2012), but the different potential interface sites vary in their accessibility. The neural interface approach consists of eliciting patterns of neuronal activation informative of the state of the limb and of events impinging upon it, typically through electrical stimulation of the neuronal tissue. Let us briefly compare and contrast interfaces with the nerve and with the brain, at the two anatomical extremes of the interface continuum.

Peripheral Interfaces Afferents can be accessed either in the residual nerve (Dhillon and Horch 2005) or in the dorsal root (Hokanson et al. 2011), where all of their cell bodies are located. Only a relatively small number of different types of mechanoreceptive afferents convey proprioceptive and cutaneous information, and the properties of these neurons are both highly stereotyped and well characterized. Furthermore, these neurons are not interconnected, so they essentially convey independent signals to the brain, which greatly simplifies stimulation strategies. The idea, then, is to attempt to reproduce natural patterns of activation in the nerve by strategically injecting small electrical currents into it, ideally through many independently controlled electrodes. The patterns of electrical stimulation can be modulated in space and time to produce naturalistic patterns of afferent activation. A variety of very powerful single input single output models have been developed to convert the output of sensors on the prosthesis into desired patterns of neuronal activation and these patterns can in theory be effected in the nerve through electrical stimulation (Dong et al. 2012; Kim et al. 2009, 2010), while other multi input multi output models have also been explored (Daly et al. 2012; Liu et al. 2011).

Cortical Interfaces A cortical interface has the advantage that it can be applied to patients with upper spinal cord injury, for whom the communication between the nerve and the brain has been

severed. Another desirable feature of cortical interfaces is that sensory systems extract behaviorally relevant information from the relatively unelaborated representation in the nerve through successive stages of processing. Indeed, individual cortical neurons encode more complex stimulus features than do their peripheral counterparts. Furthermore, cortical neurons are organized topographically, such that nearby neurons tend to respond to similar stimulus features. This organizational scheme, largely absent in the nerve, may thus be exploited in attempting to elicit artificial percepts.

There are two general approaches to conveying sensory information through a cortical interface. The first, analogous to its peripheral counterpart, consists of attempting to reproduce naturalistic patterns of neuronal activation through electrical stimulation. To the extent that patterns of activation are naturalistic, the evoked percepts will be verisimilar and thus intuitive, requiring little training on the part of the patient. Within this approach, the functional topography of the brain can be exploited. For example, information about contact location – where is the object contacting the skin? – is important for object manipulation. In intact individuals, where we feel a poke on the skin is determined by which population of neurons gets activated. Thus, information about contact location might be conveyed by stimulating small populations of somatosensory neurons, thereby eliciting a percept that is localized to a small patch of skin (Tabot et al. 2013). In amputees, the sensation is projected to a phantom limb, in tetraplegic patients to their deafferented limb. Now imagine that anytime the prosthetic thumb touches an object, stimulation is triggered through electrodes that are implanted in the thumb representation of somatosensory cortex. The evoked sensation will be projected to the phantom or deafferented thumb, which will lead to an intuitive sense of where contact happened. In fact, studies suggest that, while stimulating the neuronal representation of the thumb will be experienced on the phantom or deafferented thumb, if patients have consistent visual experience of contact with the thumb, paired with sensations experienced on

the native thumb, the sensations will start to be experienced on the prosthesis (Marasco et al. 2011). Artificial touch may thus lead to embodiment of the robotic limb! While some degree of naturalism might be achieved with a brain interface, cortical neurons are embedded in highly complex networks, and electrical stimulation of cortical tissue leads to diffuse activation of neurons with very different response properties despite the spatial organization of the brain (Histed et al. 2009). Producing truly naturalistic patterns of activation through electrical stimulation is therefore an endeavor that is doomed to failure.

With this in mind, the so-called biomimetic approach – the exploitation of existing neuronal representations – may be unnecessary. Another approach to conveying sensory feedback through a cortical interface consists of exploiting the brain's ability to learn. Indeed, the brain is known to be highly adaptable, so it is not unreasonable to hypothesize that if a systematic mapping is created between patterns of sensory activation and patterns of intracortical microstimulation, patients will learn to use this artificial sensory feedback to control the limb. Indeed, animals are able to learn to use completely arbitrary but systematic artificial sensations to guide behavior (Thomson et al. 2013; O'Doherty et al. 2011). However, the space of possible sensations that were tested in these experiments is small relative to the almost infinite space of sensory events associated with the hand and it is unclear whether the adaptation-based approach will scale up sufficiently for use in upper-limb neuroprostheses. Most likely, biomimicry and adaptation will both play critical roles in successful attempts to convey sensory feedback.

Conclusions

Multielectrode arrays have been implanted in the brain of human patients, and algorithms have been developed to decipher how these patients wish to move anthropomorphic robotic arms from signals in the motor parts of their brain (Hochberg et al. 2012; Collinger et al. 2013). In other words, these

patients can control robotic limbs by thought alone. While these studies constitute staggering examples of scientific and technological achievement, the evoked movements are slow and inaccurate, and the neuroprostheses are only viable in a laboratory setting. Given its importance in guiding movement, the incorporation of somatosensory feedback in the next generation of prostheses may bring about a major improvement in the dexterity of these limbs, and perhaps eventually may lead to a clinically viable option to restore sensorimotor function in amputees and tetraplegic patients.

Sound Localization and Experience-Dependent Plasticity

Christian J. Sumner and Robert Mill
MRC Institute of Hearing Research,
Nottingham, UK

Definition

The ability to localize sounds in space, and the way in which such a task is performed, is not fixed. If the physical cues for sound localization are altered, ability is initially disrupted. However, following experience with the new set of cues, a degree of the original performance is regained, accompanied by various changes in auditory processing.

Detailed Description

Localizing sound sources in the external world requires the integration of multiple cues. The

relative time of arrival and sound level across the two ears depend on which side of the head the sound originates from (azimuth) and frequency-dependent filtering by the head and ears that depends on the vertical angle of the sound source (elevation). For a given location these cues correspond, but not uniquely for a given frequency. Thus, information is integrated across different monaural and binaural cues and different frequency ranges. The correspondence of cue values also depends on individual's head and outer ear (pinna) size and shape and the relative state of their hearing at each ear, all of which change with age. Possibly as a consequence, the calibration of these cues in the auditory system is quite flexible. Flexibility may also be an advantage for dealing with different acoustic environments.

Experience-Dependent Changes in Sound Localization Ability

Manipulating of the cues for sound localization by altering the sound input to the ear immediately results in impaired sound localization ability. However, in most cases there is some subsequent recovery of sound localization ability over time.

Occlusion of one ear (typically with a removable ear plug) results in an immediate shift in free field azimuthal sound localization toward locations on the other side. In humans (Kumpik et al. 2010), ferrets (King et al. 2000), and owls (Knudsen 2002), sound localization ability improves over days and weeks of continued occlusion. Performance with the altered cues recovers completely in juveniles and is robust in experiments with adult ferrets and humans but does not occur in adult owls. However, even owls raised with altered cues can learn to localize correctly if normal hearing is reestablished in adulthood. Although differences in timing and level across the two ears are the dominant cues for azimuthal sound localization, in adult humans (Kumpik et al. 2010) and ferrets (Kacelnik et al. 2006), performance improvement in azimuthal sound localization appears to reflect an increased reliance on monaural spectral cues.

Modification of the vertical cues for sound localization also results in adaptation of behavioral responses. Ear molds that modify the elevation-dependent spectral filtering by the pinnae produce immediate deficits in the vertical plane. Performance is almost entirely recovered with experience (Hoffman et al. 1998). Explicit modification of binaural cues (e.g., interaural timing), azimuthal shifts, or nonlinear transforms also results in an immediate drop and subsequent improvement of localization ability, though recovery of unaltered performance is not generally complete and it is not possible to adapt to reversal of the inputs to each ear. Training also produces improvements on unaltered cues (see Wright and Zhang (2006) for a review). The immediate effect of monaural earplugging in adult humans suggests that sound localization in both azimuth and elevation relies on a rapidly updated weighting of all acoustic cues depending on their reliability (Van Wanrooij and Van Opstal 2007).

Reversal of cue manipulations generally results in recovery of the original sound localization behavior with only small aftereffects. Recovery is immediate in most cases in mammals (see Wright and Zhang 2006; Kacelnik et al. 2006) but only gradual in owls raised with monaural occlusion (Knudsen 2002). Improvement is often dependent on explicit training (Kumpik et al. 2010; Kacelnik et al. 2006) and has been observed when cues are only altered during testing sessions (see Wright and Zhang 2006).

Visual manipulations such as prism lenses that disrupt the correspondence between auditory and visual space also induce corrective changes in sound localization behavior (Knudsen 2002; Zwiers et al. 2003).

Mechanisms Underlying Changes in Perceptual Ability

Perceptual changes in sound localization have been shown to be associated with a range of different physiological changes that depend on experimental species and circumstances.

In the superior colliculus of the midbrain, there is a multisensory map of space, which plays an important role in orienting responses toward visual and auditory objects. In owls raised with one ear occluded, or with a visual displacement, a rewiring of the projection from the auditory midbrain (the inferior colliculus) occurs that ensures that spatial maps remained well aligned (Knudsen and Brainard 1991; Knudsen 2002). Realignment of space maps is also seen in the superior colliculus of ferrets raised with abnormal visual or auditory cues (King et al. 2000). However, realignment is not complete and alignment nevertheless improves once normal cues are reinstated. This is consistent with the rapid recovery of behavioral performance, as if the “default” map develops regardless. Even visual deprivation during development still results in a largely normal map. However, pinnae and conchae are required for the auditory space map to develop properly.

In purely auditory regions (inferior colliculus in the midbrain, primary auditory cortex), raising animals with a monaural hearing loss tends to result a change in binaural sensitivity in favor of the unaffected ear (see King et al. 2011). This suggests a shift toward monaural cues, rather than “rebalancing” the binaural cues.

Despite the ability of adult mammals to adapt perceptually in response to monaural occlusion, the auditory-visual space map of the midbrain does not realign in adulthood. However, there is considerable evidence that the auditory cortex and descending pathways in the auditory system are involved. Protracted deactivation of the auditory cortex which can affect sound localization often has a more profound effect on the ability to adapt behaviorally to altered localization cues (Nodal et al. 2012). The descending pathways also appear to mediate adaptation in mammals. Lesions to the descending pathway from the auditory cortex to the midbrain (Bajo et al. 2010) or efferent connections (olivocochlear) from the brainstem to the cochlea (Irving et al. 2011) do not affect normal sound localization but impair the

ability to adapt to monaural occlusion. These data are consistent with the idea that auditory spatial plasticity in adulthood reflects a change in the way different cues are used (choosing reliable ones) rather than change in the way any individual cue is computed. Possibly, the effort required to interpret altered cues places a greater reliance on the cortex and descending pathways.

Sound Localization in Mammals and Models

J. Braasch

School of Architecture, Rensselaer Polytechnic Institute, Troy, NY, USA

Definition

Models of sound localization for mammals describe or simulate the process of how the mammalian auditory system determines the position and/or spatial extent of one or multiple sound sources from cues it extracts from signals captured at the eardrums.

Detailed Description

Historical Overview

The first theories describing how the human auditory system can determine the position of a sound source appeared in the late nineteenth century after W. Thompson (1877), S. P. Thompson (1882), and Steinhauser (1877) discovered that interaural time and level differences occur between both ear signals if a sound source arrives from the side. The focus continued to be on so-called lateralization models, which explain how a sound source is perceived to the left or right based on interaural cues. The first model that describes an actual physiological mechanism of how the central nervous system localizes sound is the Jeffress model, which proposes a combination of delay lines and coincidence detectors to estimate the lateral position of a sound source based on interaural time differences. Within the same time period, better electronic devices enabled psychophysicists to better understand how the auditory system extracts localization cues. Devices like precise sine generators and circuits to produce interaural time and level differences made it possible to measure the performance of the auditory system in greater detail. One milestone was an experiment by Mills

(1958) to demonstrate that the human auditory system cannot lateralize a signal based on the interaural time differences of the left and right signal carriers above 1.5 kHz, correctly assuming that the underlying physiological mechanism can no longer utilize phase locking above this threshold. Other mammals can process interaural time differences (ITDs) of carrier signals at higher frequencies. The gerbil is known to process ITDs up to at least 3.0 kHz (Tolnai et al. 2017). Heffner (2004) and Heffner and Heffner (2018) demonstrated that the highest audible frequency of mammals, measured at 60 dB SPL, negatively correlates with the functional interaural distance, which describes the highest ITD that occurs for this species in their natural habitat (land or water). The functional interaural distance is largely dependent on the species head size, and it is likely that upper frequency threshold for ITD-based phase locking is generally higher for smaller mammals than for larger ones. For frequencies above the phase locking threshold, interaural time differences can be extracted from the signals' envelopes and used by the auditory system – e.g., see Joris and Yin (1995).

Another important factor in the development of localization models was advances in signal processing and communication theory. A milestone was reached when Cherry and Sayers (1956) described a functional localization model using a cross-correlator. In this model, cross-correlation is applied between the left and right ear signals to measure the delay and thus the ITD between both signals. In the late 1970s, computers were powerful enough to develop computational models that predict the lateral position of an auditory event precisely for a given pair of ear signals by simulating the complete pathway from the eardrums to higher stages including band-pass filter banks to mimic the basilar membrane's separation of the signals in bands of approximately a third of an octave wide (auditory bands) and simulating the stochastic processes of hair cells e.g., see Blauert and Cobben (1978). Aside from models simulating the general functionality of the localization process, models exist to simulate the underlying physiological process in greater detail, often simulating the response of a certain cell type

Sound Localization in Mammals and Models, Fig. 1 Coincidence mechanism as first proposed by Jeffress (1948)

measured in electrophysiological animal experiments. The latter are frequently termed pink box models to separate them from the functional black box models. Cai et al. (1998a, b) and Stecker et al. (2005) are good examples of this type of approach.

Understanding the mechanisms of how the auditory system determines the elevation and front/back direction of sound sources was much more difficult than understanding how the auditory system estimates lateral positions due to the complexity of the involved monaural cues. Blauert (1969/1970) was able to demonstrate that auditory systems utilize characteristic, direction-dependent frequency boosts or reductions which occur when the pinnae alter the incoming sound waves. Zakarauskas and Cynader (1993) presented an early localization model based on spectral monaural cues using the second derivative of the frequency spectrum. Later, statistical methods such as a Bayes classifier were used to predict the three-dimensional location of auditory events by analyzing both interaural and monaural cues (e.g., see Hartung 1998 and Nix and Hohmann 2006).

Jeffress Model

The Jeffress model (1948) was the first model to propose a physiological mechanism for mammalian sound localization. The core idea of the Jeffress model is the combination of delay lines and coincidence cells. In this model, two separate delay lines exist for each ear that run parallel. The

signals propagate on each line in opposite direction as shown in Fig. 1. A signal arriving at the left ear, $y_{l(m)}$, with m being the index for time, has to pass the first delay line, $l(m, n)$, from left to right. The variable n is the index for the coincidence detectors at different internal delays. A signal arriving at the right ear, $y_{r(m)}$, travels on the other delay line, $r(m, n)$, in the opposite direction. The discrete implementation of the delay lines can be described as follows:

$$l(m+1, n+1) = l(m, n); 1 \leq n < N \wedge l(m, 1) = y_{l(m)}, \quad (1)$$

$$r(m+1, n-1) = r(m, n); 1 < n \leq N \wedge r(m, N) = y_{r(m)}, \quad (2)$$

with N being the number of implemented coincidence cells. The time, t , and the internal delay, τ , can be easily estimated from the indices, m and n , and the sampling frequency, f_s , as follows: $t = (m-1)/f_s$ and $\tau = (n-(N+1)/2)/f_s$. A coincidence detector, $c(m, n)$, is activated when it receives simultaneous inputs from both delay lines at the positions that it is connected to. Each of the coincidence detectors is adjusted to a different ITD, due to the limited velocity of propagation of the signals on the delay line. For example, a sound source located in the left hemisphere will arrive at the left ear first, and therefore, the signal will travel a greater distance on the delay line than the signal for the right ear before both of them activate the coincidence detector for the corresponding ITD.

Interaural Cross-Correlation Models

Jeffress himself never specified explicitly how two spikes would coincide. Stern and Colburn (1978) later pointed out that the coincidence model can be considered to be an estimator for the interaural cross-correlation (IACC) function – which had been proposed earlier by Cherry and Sayers (1956) to estimate ITDs. To this end, they assumed that many parallel coincidence detector cells exist which are tuned to the same ITD. Then, the probability that two spikes from two opposite channels will activate a specific coincidence cell is given by the product of the number of spikes in those left and right channels, the interaural delay of which matches the internal delay of the coincidence cell. This product also appears in the running cross-correlation function, which is defined for a discrete system as follows. Note that $l(m', n)$ and $r(m', n)$ have to be determined recursively from Eqs. 1 and 2. The classical continuous form of the running cross-correlation function is

$$\Psi_{y_{lr}}(t, \tau) = \int_{t' = t}^{t + \Delta t} y_l(t' - \tau/2) \cdot y_r(t' + \tau/2) dt',$$

$$\Psi_{y_{lr}}(m, n) = \frac{1}{\Delta m} \sum_{m' = m}^{m + \Delta m} c(m', n) = \frac{1}{\Delta m} \sum_{m' = m}^{m + \Delta m} l(m', n) r(m', n),$$
(3)

with $c(m, n) = l(m, n) r(m, n)$ and the assumption that the amplitudes in the left and right channels are proportional to the number of spikes. In Eq. 3, a rectangular window of the length, Δm , was chosen, within which the cross-correlation function for each time interval is calculated. Often other window shapes, e.g., Hanning window, triangular window, and exponential window, are used. The duration of the time window, $\Delta t = \Delta m / f_s$, can be determined in psychoacoustical experiments measuring binaural sluggishness. Values come out to be on the order of tens to hundreds of milliseconds depending on the listener and measurement method (Grantham and Wightman 1978, 1979; Grantham 1982, 1979; Kollmeier and Gilkey 1990). Sayers and Cherry (1957) used the interaural cross-correlation (IACC) to determine the ITDs, and in 1978, a computational lateralization model based on IACC and the simulation of the auditory periphery was introduced independently in Blauert and Cobben (1978) and Stern and Colburn (1978). The general structure of a common cross-correlation model is shown in Fig. 2. Besides the common cross-correlation function, there are alternative ways to implement the coincidence detectors. Figure 3 shows the results of different implementations, namely, the interaural cross-correlation functions of two

Sound Localization in Mammals and Models, Fig. 2 General model structure of a binaural localization model utilizing head rotations according to Braasch et al. (2013). *HRTF* outer-ear simulation/HRTF filtering, *BM* basilar membrane/band-pass filtering, *HC* hair-cell/half-wave rectification, *ITD* and *ILD analysis* interaural time

difference (ITD) cue extraction/interaural cross-correlation, and interaural level difference (ILD) cue analysis with EI cells; remapping to azimuth angles with head-rotation compensation; binaural activity pattern analysis to estimate the sound-source positions

1-kHz sinusoidal tones with ITDs of 0 and 0.5 ms are depicted. In contrast to the models reported in Blauert and Cobben (1978) and Stern and Colburn (1978), Wolf (1991) assumed that two spikes from opposite channels would always coincide when they pass by each other on the delay lines. In this case, the output of the coincidence function is not the product of the amplitudes in the left and right channel for each delay time, but rather the minimum of those two amplitudes. The signal amplitude, then, correlates with the number of spikes within the time interval of Δt as follows:

$$c_d(m, n) = \min [l(m, n), r(m, n)]. \quad (4)$$

The output characteristics of this algorithm, Fig. 3b, are quite similar to the output characteristics of the cross-correlation algorithm, with the exception that the peaks are slightly narrower at the top. In his original work, Wolf further assumed that two spikes would be canceled out after they coincide. This approach, however, is very sensitive to interaural level differences, and, thus, the

signals in the left and right channels have to be compressed in amplitude beforehand. For this reason, Wolf used a hair-cell model (Duifhuis 1972) to transform the signal level code into a rate code.

The output of Wolf's algorithm is shown in Fig. 3c. In contrast to the cross-correlation algorithm, the peaks are very narrow, and the side peaks have vanished. Lindemann achieved a similar effect a few years earlier by introducing contralateral inhibition elements into his model. The implementation of the inhibition elements is achieved by modifying the computation of the delay lines from Eqs. 1 and 2 to

$$l(m+1, n+1) = l(m, n)[1 - c_s \cdot r(m, n)]; \quad (5)$$

$$0 \leq l(m, n) < 1,$$

$$r(m+1, n-1) = r(m, n)[1 - c_s \cdot l(m, n)];$$

$$0 \leq r(m, n) < 1, \quad (6)$$

with c_s being the static inhibition constant, $0 \leq c_s < 1$. Now the signals in both delay lines inhibit each other before they meet and reduce the amplitude of the signal in the opposite channel at the corresponding delay unit as can be seen in Fig. 4. The side peaks that are found in the plain cross-correlation algorithm in Fig. 3a are eliminated in this way. Wolf's algorithm becomes more similar to Lindemann's algorithm, if only a certain percentage of the spikes is canceled in Fig. 3e. In this case, it is not even necessary to use a probabilistic hair-cell model. If only a smaller amount of the spikes is eliminated, there is, qualitatively spoken, only a little difference in whether the spikes are inhibited/canceled before or after they coincide. It should be noted that the outcome of these inhibitory algorithms is dependent on the ILDs.

In the simulation of binaural hearing, it is sometimes advantageous to reduce the peak widths of the cross-correlation curves when determining the position of the peak. Besides employing an inhibition stage, a peak reduction can be achieved by taking the signal to a power greater than one. Figure 3f shows this procedure

Sound Localization in Mammals and Models, Fig. 3 Examples for the outputs of different coincidence detectors for a 500-Hz sinusoidal signal (a) Cross-correlation algorithm; (b) direct coincidence algorithm, spikes always interact when passing each other; (c) Wolf's algorithm; (d) Lindemann's algorithm; (e) coincidence algorithm with partly eliminated spikes after coincidence; and (f) cross-correlation algorithm taken to the power of 10 (solid lines, 0-ms ITD; dashed lines, 0.5-ms ITD)

Sound Localization in Mammals and Models, Fig. 4 Structure of the Lindemann algorithm

for the power of 10. However, by this approach, the side peaks are hardly reduced. When using the cross-correlation algorithm, not only the position of the cross-correlation peak but also its normalized height – the so-called interaural cross-correlation (IACC) coefficient or interaural coherence (IC) – can be used to gain information about the spaciousness of the environment, e.g., a room. It can be determined by taking the maximum of the normalized cross-correlation function,

$$\Psi_{y_l, r}(\tau) = \frac{\int_{t=-\infty}^{+\infty} y_l(t) \cdot y_r(t + \tau) dt}{\sqrt{\int_{t=-\infty}^{+\infty} y_l^2(t) dt \cdot \int_{t=-\infty}^{+\infty} y_r^2(t) dt}}, \quad (7)$$

with the internal delay, τ , and the left and right sound pressure signals, $y_l(t)$ and $y_r(t)$. The left panel of Fig. 5 shows an example of an IACC function of a broadband noise signal for three different positions for a frequency band centered at 434 Hz. The peak of the solid cross-correlation function is located at 0 μ s which corresponds to the position at 0°. The peak of the dashed IACC function is located at 400 μ s, which indicates an azimuth of 30°. The height of the peak depicts the coherence, that is, the degree to which both signals are similar when shifted by the corresponding internal delay, τ . In both cases, the signal is fully correlated. In the third example, depicted by a dash-dotted line, the signal is

partly decorrelated as indicated by the lower peak height of 0.6. The peak location at –600 μ s belongs to an azimuth angle of 270°. The cross-correlation coefficient correlates strongly with “spaciousness” – or auditory source width – a psychoacoustical measure for the spatial extent of auditory events and an important parameter for room acousticians (Blauert and Lindemann 1986; Okano et al. 1998). Spaciousness decreases with an increasing correlation coefficient and, therefore, with the height of the cross-correlation peak (Fig. 5).

Two-Channel ITD Models

A few years ago, the Jeffress model and with it the cross-correlation approach were challenged by physiological studies on gerbils and guinea pigs. McAlpine and Grothe (2003) and others (Grothe et al. 2010; McAlpine 2005; McAlpine et al. 2001; Pecka et al. 2008) have shown that the ITD cells for these species are not tuned evenly across the whole physiologically relevant range, but heavily concentrate on two phases of $\pm 45^\circ$. Consequently, their absolute best-ITD values vary with the center frequency that the cells are tuned to. Dietz et al. (2011, 2008) and Pulkki and Hirvonen (2009) developed lateralization models that draw from McAlpine and Grothe’s (2003) findings. It is still under dispute whether the Jeffress delay-line model or the two-channel

Sound Localization in Mammals and Models, Fig. 5 *Left:* Interaural cross-correlation functions for a sound source at three different positions in the horizontal plane. The sound sources at 0° and 30° azimuth are fully correlated; the sound source at 90° is partly decorrelated. *Right:* Interaural cross-correlation functions for a sound source at three different positions in the horizontal plane. The same stimuli as in the left panel are used, but this time, a two-channel model was applied with delay lines for $\pm 45^\circ$. The actually measured values, x_- for the

-45° -phase condition and x_+ for the $+45^\circ$ -phase condition, are shown by the “x” symbols. The simulated IACC curves were compensated for half-wave rectification. The gray curves show the actual IACC curves from the left panel. The normalized cross-correlation curves were estimated using standard trigonometric sine-cosine relationships for magnitude $A = \sqrt{x_-^2 + x_+^2}$ and phase $\phi = \arctan(x_- / x_+)$

model correctly represents the human auditory system, since the human ITD mechanism cannot be studied directly on a neural basis. However, the human auditory system evolved from smaller mammals, and for these, current theories are trending toward two-channel models (Leibold and Grothe 2015). A recent magnetoencephalography (MEG) study confirmed that the cortical representation of ITDs in the human auditory system is very similar to the cortical ITD representation in other mammals (Salminen et al. 2018). For other species, such as owls, a mechanism similar to the one proposed by Jeffress has been confirmed by Carr and Konishi (1990), but it needs to be considered that the mammalian auditory system evolved independently from those of birds and reptiles (Grothe and Pecka 2014). Opponents of the two-channel theory point out that the cross-correlation model has been tested much more rigorously than other ones and is able to predict human performance in great detail (Bernstein and Trahiotis 2002). From a practical standpoint, the result for both approaches is not as different as one might think. For the lower frequency bands, the cross-correlation functions always have a sinusoidal shape, due to the narrow width of the auditory bands – see the right panel of Fig. 5. Consequently, the whole cross-correlation function is more or less defined by two phase values 90° apart.

Models Utilizing Interaural Level Differences

Interaural level differences are the second major localization cue. They occur because of shadowing effects of the head, especially when a sound arrives sideways. For humans ILDs typically reach values of up to ± 30 dB at frequencies around 5 kHz and azimuth angles of $\pm 60^\circ$. At low frequencies, the shadowing effect of the head is not very effective, and ILDs hardly occur, unless the sound sources come very close to the ear canal entrance (Blauert 1997; Brungart and Rabinowitz 1999). This led Lord Rayleigh (1907) to postulate his *duplex theory*, which states that ILDs are the primary localization cue for high frequencies and ITDs for low frequencies. In the latter case, Lord Rayleigh assumed that unequivocal solutions for the ITDs can no longer exist for high frequencies. Then, the wavelength of the incoming sound is much shorter than the width of the head, which determines the physiological range for ITDs of approximately ± 800 μs. Mills (1958) later supported the duplex theory by demonstrating that the auditory system can no longer detect ITDs from the fine structure of signals above 1500 Hz. This effect results from the inability of the human auditory system to phase lock the firing patterns of auditory cells with the waveform of the signal at these frequencies. Meanwhile, however,

it has been shown that the auditory system can extract ITDs at high frequencies from the signals' envelopes (Joris 1996; Joris and Yin 1995), and the original duplex theory had to be revised accordingly. ILDs, denoted as α , can be computed directly from the left and right ear signals – which is typically done for individual frequency bands:

$$\alpha = 10 \log_{10} (P_l) - 10 \log_{10} (P_r), \quad (8)$$

with P_l the power of the left and P_r the power of the right signal. Reed and Blum (1990) introduced a physiologically motivated algorithm to compute ILDs based on the activity, $E(\alpha)$, of an array of excitation/inhibition (EI) cells:

$$E(\alpha) = \exp \left[\left(10^{\alpha/ILD_{\max}} \sqrt{P_l} - 10^{-\alpha/ILD_{\max}} \sqrt{P_r} \right)^2 \right], \quad (9)$$

with P_l and P_r being the power in the left and right channels, respectively, and $ILD_{\max}$ the maximal ILD magnitude that the cells are tuned to. Each cell is tuned to a different ILD. Figure 6 shows an example for a sound with an ILD of -12 dB. The curve depicts how the response of each cell is

reduced the further the applied ILD is away from the value the cell is tuned to.

Lateralization Models

Many models have been established to predict the perceived left/right lateralization of a sound which is presented to a listener through headphones with an ITD or an ILD or both. Usually, those sounds are perceived inside the head on the interaural axis with a distance from the center of the head. This distance, the so-called lateralization, is usually measured on an interval or ratio scale. The simplest implementation of a decision device is to correlate the perceived lateralization with the estimated value of a single cue, e.g., the position of the cross-correlation peak in one frequency band. This is possible, because the laterality, the perceived lateral position, is often found to be nearly proportional to the value of the analyzed cue. The decision device has to be more complex if different cues are to be analyzed or if one cue under consideration is observed in different frequency bands. A very early model that integrates information from different cues, ITDs and ILDs, is the

Sound Localization in Mammals and Models, Fig. 6 Bottom: EI-cell structure. Top: Output of the EI cells for a signal with an ILD of -12 dB

position-variable model of Stern and Colburn (1978). The authors were able to predict the perceived lateralization for a 500-Hz sinusoidal tone for all combinations of ITDs and ILDs. The left panels of Fig. 7 show the results of the position-variable model for three different combinations of ITDs and ILDs. The ITDs are measured using the cross-correlation algorithm of Fig. 7a. Afterward, the cross-correlation curve is multiplied by a delay-weighting function in order to enhance the output for small ITDs; see Fig. 7b. This is done to take into consideration that the number of neural fibers which are tuned to small ITDs is higher than those tuned to large ITDs. The delay-weighting function (Colburn 1977) is shown in Fig. 8, left panel, dotted curve. The influence of the ILDs is represented in a second function of Gaussian shape and constant width of 1778 μs , as depicted in Fig. 7c. The peak position of this second weighting is varied with the ILD of the signal. For this purpose, the signal's ILD, α , is calculated according to Eq. 8 and transferred into a corresponding ITD, τ , using a function which

can be derived from psychoacoustical data as follows:

$$\tau = 0.1\alpha - 3.5 \cdot 10^{-5} \alpha^3 [\text{ms}]. \quad (10)$$

Finally, this function is multiplied with the weighted cross-correlation function from Fig. 7b, and the centroid of the resulting function correlates with the perceived lateralization (Fig. 7d).

Localization in the Horizontal Plane

Several methods to calculate sound-source positions from the extracted binaural cues exist. One method of achieving this is to create a database to convert measured binaural cues, namely, ITDs and ILDs, into spherical coordinates. Such a database or map can be derived from a measured catalog of *head-related transfer functions* (HRTFs) of a large number of sound-source directions. Here, the binaural cues are calculated frequency-wise from the left- and right-ear HRTFs of each position. Using this database, the measured binaural cues of a sound source with unknown positions can be mapped to spherical angles. The application of the remapping method to localize a signal in the horizontal plane is discussed in detail in Braasch et al. (2013). Figure 9 shows the results of remapped cross-correlation functions and ILD-based EI cell-array functions for different frequency bands. The results were obtained using a click source signal convolved with HRTFs from a human catalog at 0° elevation.

An ongoing challenge has been to figure out how the auditory system combines the individual cues to determine the location of auditory events – in particular to answer how the auditory system performs tasks to (i) combine different cue types, such as ILDs and ITDs, (ii) integrate information over time, (iii) integrate information over frequency, (iv) discriminate between concurrent sources, and (v) deal with room reflections.

A number of detailed overviews (Stern and Trahiotis 1995; Stern et al. 2006; Braasch 2005) have been written on cue weighting, and only a

Sound Localization in Mammals and Models, Fig. 7 Results for the position-variable model (Stern and Colburn 1978) for a 500-Hz sinusoidal signal with different combinations of ITD and ILD, namely, 0 ms/0 dB (black solid line), 0 ms/15 dB (gray solid line), and 0.5 ms/15 dB (black dashed line): weighted function of (a) interaural cross-correlation functions, (b) delay-line (a) to emphasize small ITD values, (c) ILD functions, and (d) combined ITD and ILD analysis by multiplying (b) with (c) and calculating the centroid as represented by the vertical lines

brief introduction will be given here. One big question is how the auditory system weights cues temporally. The two opposing views are that the auditory system primarily focuses on the onset part of the signal versus the belief that the auditory system integrates information over a longer signal duration. Researchers have worked with conflicting cues – such as trade-off between early onset and later ongoing cues – and it is generally agreed upon that the early cues carry a heavier weight (Freyman et al. 1997; Hafter 1997; Zurek 1993). This phenomenon can be simulated with a temporal weighting function. More recently it was suggested that the auditory system does not simply blindly combine these cues but also evaluates the robustness of these cues and discounts unreliable cues. A good example for this approach is a model by Faller and Merimaa

(2004). In their model not only the positions of the cross-correlation peaks are calculated to determine the ITDs but also the coherence – as, for example, determined by the maximum value of the interaural cross-correlation function. Coherent time-frequency segments are considered to be more salient and weighted higher assuming that concurrent sound sources and wall reflections that can produce unreliable cues decorrelate the signal and thus show low coherence. Frequency weighting also applies and, in fact, the duplex theory can be seen as an early model where ITD cues are weighted high at low frequencies, and ILD cues dominate at higher frequencies. Newer models have provided a more detailed view of how ITDs are weighted over frequency. Different curves have been obtained for different sound stimuli (Akeroyd and Summerfield 1999;

Sound Localization in Mammals and Models, Fig. 10 Output of Stern et al.'s model (Stern et al. 1988) to a band-pass noise, 700-Hz center frequency, 1000-Hz bandwidth, 1.5-ms ITD. The *top-left panel* shows the

output without centrality and straightness weighting, the *top-right panel* with centrality weighting only, and the *bottom panel* with centrality and straightness weighting

Raatgever 1980) including straightness and centrality weighting (Stern et al. 1988, see Fig. 10).

Localization Models Using Monaural Cues

A model proposed in 1969–1970 (Blauert 1969/1970) analyzes monaural cues in the median plane as follows. The powers in different frequency bands, the directional bands, are analyzed and compared to each other. Based on the signal's angle of incidence (front, above, or back), the pinnae enhance or deemphasize the power in certain frequency regions, which are the primary localization cues for sound sources within the median plane. Building on this knowledge, Blauert's model uses a comparator to correctly

predict the direction of the auditory event for narrowband signals. Zakarauskas and Cynader (1993) developed an extended model for monaural localization, which is based on the assumption that the slope of a typical sound source's own frequency spectrum only changes gradually with frequency, while the pinnae-induced spectral changes vary more with frequency. The model primarily uses the second-order derivative of the spectrum in frequency to determine the elevation of the sound source – assuming that the sound source itself has a locally constant frequency slope. In this case, an internal, memorized representation of a sound source's characteristic spectrum becomes obsolete. Baumgartner et al. (2013) created a probabilistic localization model that analyzes inter-spectral differences (ISDs) between the internal representations of a perceived sound

and templates calculated for various angles. The model also includes listener-specific calibrations to 17 individual listeners. It had been shown earlier that, for some cases, ISDs can be a better predictor for human localization performance than the second-order derivative of the spectrum (Langendijk and Bronkhorst 2002). By finding the best ISD match between the analyzed sound and the templates, Baumgartner et al.'s model is able to demonstrate similar localization performance as human listeners.

In contrast to models which do not require a reference spectrum of a sound source before it is altered on the pathway from the source to the ear, it is sometimes assumed that listeners use internal representations of a variety of everyday sounds to which the ear signals are compared to in order to estimate the monaural cues. A database with the internal representations of a high number of common sounds has not been implemented in monaural model algorithms so far. Some models exist, however, that use an internal representation of a single reference sound, e.g., for broadband noise (Hartung 1998) and for click trains (Janko et al. 1997).

Three-Dimensional Localization Models

In free field, the signals are filtered by the outer ears, and the auditory events are, thus, usually perceived as externalized in three-dimensional space. One approach to estimate the position of a sound source is to train a neural network to estimate the auditory event from the interaural cues rather than to combine the cues analytically, e.g., Hartung (1998); Janko et al. (1997); Ma et al. (2017); Xu et al. (2019). When applying such a method, the neuronal network has to be trained on test material. The advantage of this procedure is that often very good results are achieved for stimuli that are very similar to the test material. The disadvantages are, however, the long time necessary to train the neural network and that the involved processing cannot easily be described analytically.

The frequency-dependent relationship between binaural cues and the azimuth and

elevation angles can be determined from a catalog of HRTFs which contains the HRTFs for several angles. Spatial maps of these relationships can be set up, using one map per analyzed frequency band. It should be noted at this point that, although neurons that are spatially tuned were found in the inferior colliculus of guinea pigs (Hartung 1998) and in the primary field of the auditory area of the cortex of cats (Middlebrooks and Pettigrew 1981; Imig et al. 1990), a topographical organization of those types of neurons could not be shown yet.

Those types of localization models that analyze both ITDs and ILDs either process both cues in a combined algorithm (e.g., Stern and Colburn 1978) or evaluate both cues separately and combine the results afterward, in order to estimate the position of the sound source (e.g., Janko et al. 1997; Nix and Hohmann 2000, 2006; Hartung 1998). In Janko et al. (1997), it is demonstrated that, for filtered clicks, both the ITDs and ILDs contribute very reliable cues in the left–right dimension, while in the front–back and the up–down dimensions, ILDs are more reliable than ITDs. The findings are based on model simulations using a model that includes a neural network. The network was trained with a back-propagation algorithm on 144 different sound-source positions in the whole sphere, the positions being simulated using HRTFs. The authors could feed the neural network with either ITD cues, ILD cues, or both. Monaural cues could also be processed.

Precedence Effect Models

Dealing with room reflections remains to be one of the biggest challenges in communication acoustics across a large variety of tasks including sound localization, sound-source separation, as well as speech and other sound feature recognition. Typically, models use a simplified room impulse response, often only consisting of a direct sound and a single discrete reflection to simulate the precedence effect. Lindemann (1986a, b) took the following approach to the inhibition of location cues coming from reverberant information. Whenever his contralateral inhibition algorithm

detects a signal at a specific interaural time difference, the mechanism starts to suppress information at all other internal delays or ITDs and thus solely focuses on the direct source signal component. The Lindemann model relies on onset cues to be able to inhibit reflections, but fairly recently, Dizon and Colburn (2006) have shown that the onset of a mixture of an ongoing direct sound and its reflection can be truncated without affecting the precedence effect.

Based on their observation that human test participants can localize the on- and offset-truncated direct sound correctly in the presence of a reflection, Braasch and Blauert (2011) and Braasch (2013) proposed an autocorrelation-based approach. The model reduces the influence of the early specular reflections by autocorrelating the left and right ear signals. Separate autocorrelation functions for the left and right channels determine the delay times between the direct sound source and the reflection in addition to their amplitude ratios. These parameters are then used to steer adaptive deconvolution filters to eliminate each reflection separately. It is known from research on the *apparent source width* of auditory objects that our central nervous system is able to extract information about early reflections (Barron and Marshall 1981), which supports this approach. The model is able to simulate the experiments from Dizon and Colburn's (2006) study, and the revised model is able to predict the lateral positions and delays of early reflections from a running signal (Braasch 2016).

Further, it has been shown that for short test impulses such as clicks, localization dominance can be simulated using a simple cross-correlation algorithm without inhibition stages when a hair-cell model is included in the preprocessing stage (Hartung and Trahiotis 2001). To this end, an adaptive hair-cell model (Meddis et al. 1990) was employed. Parts of the precedence effect are, thus, understood as results of sluggish processing in the auditory periphery. Further models to simulate the adaptive response of the auditory system to click trains, "buildup of the precedence effect," can be found in Zurek (1987) and Djelani (2001).

Localization in Multiple-Sound-Source Scenarios

In general, physiologically motivated computational localization models have difficulties to localize two or more independent sound sources. A number of binaural localization models exist that are specialized to localize a test sound in the presence of distracting sound sources, but these models typically follow more traditional signal processing methods and do not represent the neural mechanism with the same details some of the previously mentioned models do. In one class of models, termed "cocktail-party processors," the information on the location of the sound sources is used to segregate them from each other (e.g., Bodden 1992; Lehn 2000). These algorithms can be used to improve the performance of speech recognition systems (Rateitschek 2000). For further improvement of binaural models, it has been proposed to implement an expert system, which completes the common signal-driven, bottom-up approach (Blauert 1999). The expert system should include explicit knowledge on the auditory scene and on the signals – and their history. This knowledge is to be used to set up hypotheses and to decide if they prove to be true or not. As an example, front-back differentiation can be named. The expert system could actively test whether the hypothesis that the sound source is presented in the front is true or false, by employing "auditory scene analysis (ASA)" cues. It could further analyze the monaural spectrum of the sound source in order to estimate the influence of the room in which the sound source is presented, determine the interaural cues, and even evaluate cues from other modalities, for example, visual cues. The expert system would evaluate the reliability of the cues and weight them according to the outcome of the evaluation. In the future, once the computational power increases furthermore and more knowledge on the auditory system is gained, one can expect that binaural models will become more complex and include the simulation of several binaural phenomena rather than the simulation of only a few specific effects.

Matters become more complicated if it is not clear how many sound sources currently exist.

Then the cues do not only have to be weighted properly but also assigned to the corresponding source. Here one can either take a target + background approach (Nix and Hohmann 2006), where only the target sound parameters are quantified and everything else is treated as noise, or one can attempt to determine the positions of all sound sources involved (Braasch 2002, 2003; Roman and Wang 2008; Deshpande and Braasch 2016; Mi et al. 2016; Zhang and Wang 2017). Often, in models that segregate the individual sounds from a mixture, the positions of the sources are known a priori, such as in Bodden (1993) and Roman et al. (2006).
